# Numerical Toolbox for Verified Computing II

## Advanced Numerical Problems

This is a draft version which still contains errors.

# Preface

To L. Kronecker we owe the remark, "God created the natural numbers, all else is man made." This difference is reflected in computers, where arithmetic on the natural numbers may be performed exactly, while for all else, only approximately.

Traditionally in Scientific Computing, the computer is only capable of computing approximate solutions to a problem. Even though approximations are often satisfactory, they may nevertheless be inaccurate or even completely wrong. With traditional floating-point-arithmetic, it is usually very difficult to tell when something has gone wrong simply by looking at the numerical results.

In contrast, this treatise aims to do rigorous mathematics with the computer using floating-point numbers. For that purpose we enhance the mathematical power of the digital computer by defining and using the ideal computer. Instead of reducing all calculations to the four basic arithmetic operations for floating-point numbers we require twelve fundamental data types or mathematical spaces with operations of highest accuracy in a computing environment. We also require a number of elementary functions of highest accuracy for four basic data types. In case the available real computer differs from the required ideal computer the missing operations can be simulated be use of the available integer arithmetic. Programming environments which provide these operations (the XSC-languages) are available.

The twelve fundamental data types or mathematical spaces of the ideal computer consist of the four basic data types real, complex, interval and complex interval and the vectors and matrices over these types. All computer operations for these types are directly defined by the concept of "semimorphism":

If $M$ is any one of these twelve spaces and $N$ its computer-representable subset, and if $\circ$ is any arithmetic operation in $M$, then the corresponding computer operation $\boxed{\circ}$ in $N$ is defined by

$$(RG) \quad a \boxed{\circ} b := \Box(a \circ b) \quad \text{for all } a,b \in N$$

where $\Box : M \to N$ is a mapping from M onto N, called a rounding, with the following properties:

| | | | |
|---|---|---|---|
| $(R1)$ | $\Box(a) = a$ | for all $a \in N$ | (projection) |
| $(R2)$ | $a \leq b \Rightarrow \Box(a) \leq \Box(b)$ | for $a,b \in M$ | (monotonicity) |
| $(R3)$ | $\Box(-a) = -\Box(a)$ | for all $a \in M$ | (antisymmetry) |

This means that every computer operation is performed in such a way that it produces the same result as if the mathematically correct operation were first performed and the exact result then rounded into the computer-representable subset. This rule is optimal in the sense that there is no better computer-representable approximation to the true result with respect to the prescribed rounding. $(R3)$ imposes

the property of symmetry on $N$, i. e. if $a \in N$, then $-a \in N$.

For the interval spaces among our twelve fundamental data types the order relation in $(R2)$ is the subset relation. A rounding from any interval set $M$ onto its computer-representable subset $N$ is defined by properties $(R1), (R2)$ (with $\leq$ replaced by $\subseteq$ ), plus the additional property

$(R4)$ $\quad a \subseteq \Box(a) \quad$ for all $a \in M \quad$ (inclusion)

These interval roundings are also antisymmetric, that is, they satisfy $(R3)[K], [KM]$.

This definition of Computer Arithmetic by the concept of semimorphism should be used as an axiomatic definition of computer arithmetic in the context of programming languages. This is the case in the XSC languages.

A careful analysis of the requirements of semimorphisms is given in $[K], [KM]$. Many properties of both the order structure and the algebraic structure are invariant under a semimorphism. For more details, refer to $[K], [KM]$. All semimorphic computer operations are of 1 ulp accuracy. 1/2 ulp is achieved in the case of rounding to nearest. It is ultimately shown that semimorphic operations for the twelve fundamental data types of the ideal computer can be provided if, on a low level, preferably in hardware, 15 fundamental operations are available: the five operations $+, -, *, /, \bullet$, each one with the three roundings $\Box, \bigtriangledown, \bigtriangleup$. Here $\bullet$ means the dot procuct of two vectors, $\Box$ is a monotone, antisymmetric rounding, e. g. rounding to nearest, and $\bigtriangledown$ and $\bigtriangleup$ are the monotone downwardly and upwardly directed roundings from the reals into the floating-point numbers. All 15 operations $\circ \in \{+, -, *, /, \bullet\}$ are defined by $(RG)$.

These 15 fundamental operations are found in a variety of programming systems [PASCAL-XSC, ACRITH-XSC, C-XSC, FORTRAN-XSC]. Twelve of the 15 operations are provided by the IEEE standards $[,], \circ \in \{+, -, *, /\}$. These standards also prescribe specific data formats. By adding just three more operations, all arithmetic operations in the basic product spaces of mathematics can be performed with 1 or 1/2 ulp accuracy in each component. The concept of semimorphism is not bound to specific data formats.

In Numerical Analysis, the dot product is ubiquitous. It appears in complex arithmetic, vector or matrix arithmetic, multiple precision arithmetic, and iterative refinement techniques, among many other places.

The arithmetic of the ideal computer has been implemented in hardware, in firmware, and in software on many different platforms and has been available since the early 1980's. The accumulation of products in a long fixed-point register allows an easy realization of the optimal dot product as defined by $(RG)$. Besides being always accurate, fixed-point accumulation in hardware turns out to be at least as fast

as a customary implementation using floating-point operations. Several intermediate steps of the latter as composition, decomposition, normalization, and rounding of floating-point values as well as unnecessary load and store operations become gratuitous, if accumulation is performed into a fixed-point register.

Intervals bring the continuum into the computer and open a new dimension in Numerical Analysis. An interval between two floating-point numbers describes the continuum of real numbers between these floating-point bounds. Roughly speaking, interval arithmetic brings guarantees into computation while the scalar or dot products deliver high accuracy. The mathematical insight into the fundamental principles of computer arithmetic of the ideal computer and the technology to realize them in hardware have been available for many years and should be common knowledge by now. The arithmetic of the ideal computer makes numerical computations more reliable and allows computers to do real mathematics.

In this volume a number of standard problems of Numerical Analysis are treated. All methods, algorithms and routines provide highly accurate verified enclosures of the solution or terminate with the answer that no correct solution could be found. In case of success in general even existence and uniqueness of the solution is established by the algorithm.

Among the problems that are dealt with are linear systems of equations with real, complex, interval and complex interval coefficients, sparse linear systems, eigenvalue problems, computation of the matrix exponential, numerical quadrature, staggered arithmetic, automatic differentiation and Taylor arithmetic, polynomials of several variables, and arithmetic for long reals and long real intervals. For all these algorithms the arithmetic of the ideal computer, as discussed above is essential. Although all algorithms are well designed and based on long experience the main purpose of this book is to provide sample solutions and to stimulate further research.

By way of example we discuss two of the methods that are described in the following chapters a little more closely. This demonstrates that the use of the ideal computer and appropriate programming environments are essential.

Staggered arithmetic is a very elegant way providing a long real or long real interval arithmetic. A variable of type staggered is just an array of reals, the sum of which does not fit into a single floating-point number. In the ideal case the components of the array do not overlap digitwise. Addition, subtraction and accumulations of staggered variables are performed by adding them into the long accumulator (which is a fixed-point register). Multiplication is just a dot product. Division is executed through a simple iterative scheme. A local variable rules the precision (or number of components) of variables of type staggered. This local variable can be enlarged or decreased at any time during a calculation. Thus the working precision of a program part can easily be adapted to obtain a desired accuracy of the result. The compu-

tation of the matrix exponential in chapter 6 is based on staggered arithmetic.

Staggered arithmetic is a very fast way to perform a long real arithmetic if the computation of dot products is supported by hardware. It can be used to speed up many programs of computer algebra.

As a second example we mention numerical quadrature. Most sophisticated methods have been developed in Numerical Analysis to control the step size by so called adaptive strategies. Traditionally all these methods are based on error estimates which are obtained by comparing computed approximations of different quadrature formulas. The 15th rule in case of Simpson's method is the simplest such test. All these methods may easily fail. They depend essentially on the reliability of the computed approximations.

Validated numerical quadrature begins with an evaluation of the remainder term of the quadrature formula. Depending on its size, the order of the method, the step size and/or the working precision can now be adapted. Evaluation of the remainder term needs the arithmetic of the ideal computer and appropriate programming support. All this is available for instance under PASCAL-XSC. Enclosures of the remainder term are obtained by automatic differentiation or Taylor-arithmetic. These techniques are discussed in chapters 4 and 7. The corresponding operators are somehow part of the runtime system of PASCAL-XSC. The user just has to specify his variables as being, for instance, of type interval taylor. Then the compiler computes enclosures of the taylor coefficients out of the expresssion for the function. As soon as the remainder term is under a given accuracy threshold the quadrature formula is evaluated in interval arithmetic. This is just an interval dot product. The sum of both gives a validated enclosure of the integral.

# Introduction

## 1.1 On the Purpose of Result Verification

Classical numerical methods programmed on a computer in floating-point arithmetic deliver approximations to solution(s) of the problems which they are supposed to 'solve'. It lies in their approximative nature that they cannot even address the question whether the problems they treat have a solution at all – or none or even several. In this sense these methods, or at least the corresponding computer programs, are strictly speaking only heuristic and their results do not carry any mathematical information – only hints at best.

The reasons for this situation are obviously an imprecise arithmetic on the computer – i.e. rounded floating-point arithmetic with a *finite* set of numbers only – and the additional errors which are introduced by many numerical methods like truncation errors due to stopping an iteration, discretization errors in the treatment of differential or integral equations and the like. The combination of all these errors seems to make it impossible to obtain rigorous mathematical results from a computer program where all or part of these errors come into play.

Only computer programs which use some sort of exact arithmetic like integer or rational arithmetic and which do not commit any truncation or discretization error, e.g. by carrying out symbolic computations like in computer algebra systems, are commonly believed to produce mathematically rigorous results.

Among numerical analysts and users of numerical software it is unfortunately not common knowledge that methods and computer programs which contain these sources of errors may nevertheless produce mathematically *rigorous* results. The reason for this is that floating-point arithmetic can be defined in a mathematically clean way which includes precisely defined roundings and thus the result of floating-point computations is just as reliable as that of integer or rational computations. However, in contrast to the latter, the 'exactness' of such a precisely defined floating-point arithmetic is not that it computes the exact result of an operation, but rather that it can be used to compute exact *bounds* for the result of an operation or a whole sequence of operations. Obtaining such mathematically safe bounds for results is achieved by the proper use of suitable directed roundings. For example, refer to Kulisch, [210], and Kulisch/Miranker, [211], for such a mathematically sound basis of computer arithmetic.

Another mathematical subject which may be treated independently of computers (but reveals its true power only when used on computers as we will see shortly) is

interval arithmetic. This kind of arithmetic can be interpreted as a calculus of inequalities – thus formalizing what every analyst is doing with pencil and paper. For example, interval addition $[a,b]+[c,d] = [a+c, b+d]$ is just a compact notation of the argument "if $a \leq x \leq b$ and $c \leq y \leq d$ then $a+c \leq x+y \leq b+d$". Similarly, the interval evaluation of an elementary function, the natural logarithm, say, $ln([a,b]) = [ln(a), ln(b)]$ is just a short notation for "if $a \leq x \leq b$ then $ln(a) \leq ln(x) \leq ln(b)$". The great advantage of such a *calculus of inequalities* is quite obvious, since now it is easy to compute bounds for functions defined by more complicated expressions. This fundamental property of interval arithmetic is also called *inclusion monotonicity*. For details on interval arithmetic, see [247], [248], [13], [256].

Applying interval arithmetic with pencil and paper only would certainly be a very unpleasent and error-prone task. However, in connection with the previously discussed subject, namely floating-point arithmetic with suitably defined roundings, the basic objective of interval arithmetic can still be maintained in a mathematically rigorous way: to obtain true bounds for the result of each operation. On a computer these bounds will of course always be floating-point numbers. For example, if $\bigtriangledown r$ means the largest floating-point number less than or equal to $r$ (rounding downwards) and $\bigtriangleup r$ means the smallest floating-point number greater than or equal to $r$ (rounding upwards) then the inequality $a \leq x \leq b$ can be represented on the computer as $x \in [\bigtriangledown a, \bigtriangleup b]$. This interval is a slight coarsening of the original inequality, at least if $\bigtriangleup b \neq b$ or $\bigtriangledown a \neq a$. We say the real interval $[a,b]$ has been rounded outwards to the smallest interval $[\bigtriangledown a, \bigtriangleup b]$ whose bounds are floating-point numbers and which contains $[a,b]$.

Now each single operation on the computer has to be realized with the same philosophy: instead of computing the exact result, we compute an interval with floating-point bounds containing the exact result. We call such an arithmetic a *machine interval arithmetic* – obviously the concept of inclusion monotonicity carries over to a machine interval arithmetic. Thus, using machine interval arithmetic we are able to deduce *numerically on the computer* properties and results for a continuous set of numbers ( e.g. intervals ) and consequently we are also able to perform mathematical operations on and make mathematical statements about continuous sets in other mathematical spaces like $\mathbb{R}^n$ and even in function spaces.

This is the elementary but extremely important basis on which in the last two to three decades many numerical methods have been developed which by use of interval analysis obtain results containing the true solution of the underlying problems. Results in this sense are always intervals (in a suitable space) which are mathematically verified to contain the unknown solution. We call such methods *self-validating methods* or *methods with result verification*.

This verification is a direct consequence of inclusion monotonicity in the case where the problem can be solved by just a sequence of operations of interval arithmetic. However, if the problem to be solved contains some equation(s) with one or more unknowns or if we have problems in function spaces containing differentials and/or integrals then these self-validating methods must use some mathematical theorem(s) to verify that the computed intervals contain the solution. Ideally it should be possible to verify the hypothesis of such theorems with the help of the

computer itself. In this case the computation of the enclosing intervals and the verification that they contain a solution can both be carried out on the computer.

One typical class of theorems which can be checked on a computer are fixed-point theorems which require that a function $f$ maps some set $U$ into itself: $f(U) \subseteq U$. Such a condition can be verified on a computer in the following way. Compute an interval $[U]$ which contains the set $U$. Next compute an interval evaluation $f([U])$, i.e. compute an interval $[V]$ containing all possible values $f(u)$ for $u \in [U]$. Very often obtaining such an interval evaluation of $f$ over $[U]$ is straightforward. Finally we check whether $[V]$ is contained in $U$. If this is the case then we have $f(U) \subseteq f([U]) \subseteq [V] \subseteq U$ which proves that the hypotheses $f(U) \subseteq U$ is satisfied and this can be checked completely on the computer.

If there are additional hypotheses in the theorem it may perhaps also be possible to check them on the computer or, if this is not the case, the self-validating method must be designed in such a way that it admits only functions $f$ which satisfy the additional hypotheses. E.g. if we use the Banach fixed-point theorem and we do not have a method to compute an upper bound for the Lipschitz-constant for $f$ then we have to design our algorithm such that only functions $f$ with Lipschitz-constant smaller than 1 are admitted. In the other case also this second hypotheses may be checked by the computer itself. Similarly, when using Brouwer's fixed-point theorem, we must make sure that the self-validating method uses only continuous functions. The computational part of this theorem, $f(U) \subseteq U$, can be tested as described above.

When the hypotheses of such a theorem are verified to be true by use of a computer then of course the assertions of the theorem are true also and in the case of a fixed-point theorem this means that a fixed-point exists, i.e. that $u = f(u)$ has a solution (which might even be unique, depending on which theorem precisely we are using). In this case it is no exaggeration to state that the existence of a solution has been verified by the computer since the most essential part of the work was carried out by interval computations (namely to show that $f(U) \subseteq U$).

Other classes of theorems can also be accessible for interval computations. E.g. theorems which provide bounds for eigenvalue problems need not be (and usually are not) of fixed-point type. Nevertheless, many of them can be used to compute rigorous bounds for eigenvalues. One simple example here is the Gerschgorin circle theorem (see e.g. [309] and Section 3.3).

Writing software which implements such methods is usually much more difficult than writing software in classical numerics where only approximations are computed. Since the result of the program should have mathematical rigour it is necessary that the complete program be designed just as if it were a mathematical proof. One single roundoff error in the wrong place might destroy the whole result completely!

Another difficulty is that the common classical programming languages are in general unsuited for writing software like this since they very often lack of the necessary clean floating-point arithmetic and also of many other features which we will shortly discuss in the next subsection.

The purpose of this treatise therefore is to demonstrate to the expert and the almost-expert how such self-verifying methods can be implemented and to furnish

the users which are less interested in the theory but still want to apply these methods with programs that can be used like a traditional software library, but have much stronger results: when they compute a result, this result is verified to be correct. If no result is produced, the program says that it cannot solve the problem within the given limits of resources (time, precision, memory, etc.).

In addition to the verification aspect our methods and programs often achieve highly accurate results by using an additional operation, the so-called *exact scalar product*, which is not present in classical computer arithmetic and programming languages. In [210] and [211] it is shown that with this additional operation the computer arithmetic can be made optimal in many mathematical product spaces. However, the use of this new operation, which is implemented by supplying a data type `dotprecision` in PASCAL-XSC, representing a long accumulator, is also unusual for many programmers. Therefore many methods and programs in this treatise are also intended to demonstrate the efficient use of this new operation and data type and to show how it can be used to achieve flexibility in the computational precision although only one real format is actually being used.

## 1.2 On the Programming Language used in this Treatise

Almost all presently available programming languages do not offer a clean floating-point arithmetic in the sense described in the previous section. Even though most computers nowadays are equipped with IEEE arithmetic in hardware, which is a computer arithmetic standard including all features mentioned above except the exact scalar product, the programming languages usually have no or only very limited access to such important features like e.g. rounding control.

There exist also only few programming languages which allow the definition of new operators or which support dynamic arrays. Both of these features are very important for writing mathematical computer programs. They help very much in keeping the program code short and compact which is essential when it comes to checking a program for correctness. User defined operators allow a natural mathematical notation instead of an endless list of subroutine calls, whereas dynamic arrays make it possible to use always exactly the correct array sizes thus being free of caring about unused array elements and passing array dimensions as parameters to many procedures and functions. Programs using such features are far easier to write, to maintain and to check for correctness.

Another aspect from the mathematical point of view is that a compiler should be very serious about checking as many error conditions as possible in order to avoid any unintended programming errors both during compile time and during runtime of the programs. Many systems e.g. do not allow index checking for arrays or even overflow detection of integer arithmetic. Not being notified about such possible error conditions is a severe lack of security and makes it often very tedious to find programming errors and fixing bugs.

From these aspects the choice of PASCAL-XSC for our programs is nearly the only possibility since with this programming language we have an operator concept, a clean floating-point arithmetic with access to directed roundings, interval, complex and complex interval arithmetic, reliable standard functions, dynamic arrays and many more necessary and useful features.

One especially important feature which is not even present in all members of the -XSC family ( PASCAL-, ACRITH-, C- and FORTRAN-XSC ) are the scalar product expressions which simplify the use of the exact scalar product to a large extent. Also the availability of the data type `dotprecision` representing a long accumulator distinguishes PASCAL-XSC (and the other -XSC languages) from all other programming languages.

Another aspect is that at least at the moment PASCAL-XSC is the most portable system among the -XSC languages which is also important from the point of view of program correctness, since changes in a program are not necessary as it is ported from one system to another. Thus no errors can be introduced by adapting programs to new platforms.

The complete language definition of PASCAL-XSC is contained in the Language Reference Manual, see [173] and [174].

## 1.3 On the Problems discussed in this Treatise

We assume that the reader is familiar with the basics of interval arithmetic which can be found in [247], [248], [13], [256], see also [124]. A deeper knowledge of the various topics treated here is not necessary (though sometimes it might help more). For each problem that we treat we start with a discussion of the theoretical background and of the algorithm which we want to implement. This discussion should suffice to understand the method and its implementation. Example programs show how the method should be used in practice.

In Chapter 2 we start with the discussion of systems of linear equations. This chapter is divided into two parts, the first one treating systems with full coefficient matrices and the second part systems with banded coefficient matrix. For full systems we also consider the over- and under-determined cases as well as the problem of computing inverse matrices and pseudo inverse matrices. In all cases we present algorithms which compute verified enclosures for the solutions. These algorithms will be extended to all four basic data types: real, interval, complex and complex interval. The algorithms for full systems are originally designed by Rump, [280], [285], whereas in the second part of this chapter for systems with band matrices we modify this algorithm by introducing a new method for the solution of triangular systems with band matrices.

In Chapter 3 eigenvalue problems are treated. Here again the method for ordinary eigenvalue problems are from Rump, [280], [285], and the method for the general eigenvalue problem is a simple generalization of this method. Whereas this method is iterative and needs approximate eigenvalues and eigenvectors as starting values for the iteration, we do not need such values for the method for the symmetric

eigenvalue problem. The method for the symmetric case is from Lohner, [231], and can also be generalized to Hermitian eigenvalue problems. The basic principle of this method is to compute an approximate eigensystem, transforming the original matrix with this system and computing eigenvalue enclosures from the transformed system by use of the Gerschgorin circle theorem.

Automatic differentiation is a relatively new tool in numerical analysis which makes is possible to compute derivative values without truncation errors as e.g. with divided differences. In Chapter 5 we present several variants of automatic differentiation such as the computation of Taylor-coefficients, the computation of gradients using the so-called reverse mode of automatic differentiation which is very fast and a similarly fast method for the computation of directional derivatives. In all cases the use of interval arithmetic permits us even to *enclose* the values of the derivatives.

Chapter 5.3.5 contains the description and implementation of a high precision arithmetic in so-called *staggered correction format*. This is an excellent example for the great flexibility in precision which we can achieve when we make use of the long accumulator despite of the fact that we have only one data format available for real numbers. Of course this staggered format can also be used to represent high precision intervals which makes it an ideal tool for the computation of highly accurate results even for ill-conditioned problems.

In Chapter 10 we present some simple methods for the verified computation of definite integrals. Here we will make use of the automatic differentiation module from Chapter 5 for the computation of Taylor coefficients to compute enclosures for the remainder terms of the numerical integration rules. We discuss the trapezoidal rule, Simpson's rule and Romberg integration. For each of these rules explicit error terms are known which contain higher derivatives of the integrand evaluated at unkown intermediate points. It turns out that the combination of interval arithmetic and automatic differentiation is an exceptionally well suited tool in this case, since an interval can be used to enclose the unknown intermediate argument and automatic differentiation can be used to compute the high derivative (i.e. the Taylor coefficients) over this interval thus obtaining a rigorous estimate of the error term. For the trapezoidal and Simpson's rule we will use fixed step sizes only, however, for Romberg integration we will develop a simple adaptive step size control which is not intended to be optimal in any sense but which still is powerful enough to obtain satisfying results for quite difficult integrals.

# Chapter 2

# Systems of Linear Equations

One of the most frequent tasks in Numerical Analysis is the solution of Systems of linear equations

$$Ax = b \tag{2.1}$$

with an $n \times n$ matrix $A$ and a right hand side $b \in \mathbb{R}^n$. Many different numerical algorithms contain this task as a subproblem.

As a generalization to this problem with a square matrix we often encounter *over-* or *under-determined* systems, i.e. systems where $A$ is not a square, but rather an $m \times n$ matrix with $m > n$ in the over- and $m < n$ in the under-determined case. In the over-determined case a vector $x \in \mathbb{R}^n$ is sought whose residuum $b - Ax$ has minimal Euclidian norm whereas in the under-determined case a solution $x \in \mathbb{R}^n$ of (2.1) is sought which has minimal norm.

Also the inversion of the matrix $A$ is a problem of this type. Here, the right hand side of (2.1) has to be replaced by the $n \times n$ identity matrix $I$ and the solution $X$, which is a matrix now, will be the inverse $A^{-1}$ of $A$. In the over- or under-determined case this matrix $X$ will be the Moore-Penrose pseudo inverse $A^+$ of $A$ (if $A$ has full rank).

There are numerous methods and algorithms which compute approximations to the solution $x$ in floating-point arithmetic. However, usually it is not clear how good these approximations are, or if there exists a unique solution at all. In general, it is not possible to answer these questions with mathematical rigour if only floating-point approximations are used. These problems become especially difficult if the matrix $A$ is ill conditioned.

In this Chapter we will present some algorithms which answer the questions about existence and accuracy automatically once their execution is completed successfully. Even very ill conditioned problems can be solved with these algorithms. Most of the algorithms presented here can be found in [285]. All algorithms work for all four basic numerical PASCAL-XSC data types: *real, interval, complex* and *complex interval*.

We divide this Chapter into two parts, the first part deals with systems whose coefficient matrix is dense, whereas the second part treats systems with banded matrices as coefficient matrix.

# 2.1 Systems with Dense Matrices

## 2.1.1 Introduction

Here we assume the coefficient matrix $A$ in (2.1) to be dense, i.e. in a PASCAL-XSC program we use a square matrix of type *rmatrix, imatrix, cmatrix* or *cimatrix* to store $A$ and we do not consider any special structure of the elements of $A$.

Our goal is to write a PASCAL-XSC program that *verifies the existence* of a solution and *computes an enclosure* for this solution for each of the following types of problems:

(s) compute an enclosure for the solution of system (2.1) for a *square* $n \times n$ matrix $A$.

(o) compute an enclosure for the solution of system (2.1) in the *over-determined* case, i.e. for an $m \times n$ matrix $A$ where $m > n$.

(u) compute an enclosure for the solution of system (2.1) in the *under-determined* case, i.e. for an $m \times n$ matrix $A$ where $m < n$.

(S) compute an enclosure of the *inverse* $A^{-1}$ of $A$.

(O) compute an enclosure of the *pseudo inverse* $A^{+}$ of $A$ in the *over-determined* case, i.e. for an $m \times n$ matrix $A$ where $m > n$.

(U) compute an enclosure of the *pseudo inverse* $A^{+}$ of $A$ in the *under-determined* case, i.e. for an $m \times n$ matrix $A$ where $m < n$.

We also want these six problems to be solved for all four basic numerical PASCAL-XSC data typtes: *real, interval, complex* and *complex interval*. In the following Section 2.1.2 we will briefly outline the solution methods. The corresponding algorithmic description can be found in Section 2.1.3 and the PASCAL-XSC program code will be presented in Section 2.1.5.

## 2.1.2 Theoretical Background

In this section we give only a brief summary of the theory of the enclosure methods for our six problems. A more detailed presentation can be found e.g. in [285].

Starting with problem (s) we first assume that we have an approximate solution $\tilde{x}$ and an approximate inverse $R$ of the square matrix $A$. Rather than computing an enclosure for the solution directly we will try to enclose the error of the approximate solution which yields much higher accuracy. The error $y = x - \tilde{x}$ of the true solution

$x$ satisfies the equation

$$Ay = b - A\tilde{x} \tag{2.2}$$

which can be multiplied by $R$ and rewritten in the form

$$y = R(b - A\tilde{x}) + (I - RA)y \tag{2.3}$$

or with $f(y) := R(b - A\tilde{x}) + (I - RA)y$

$$y = f(y) \ . \tag{2.4}$$

This is an equation in fixed point form for the error $y$. If $R$ is a sufficiently good approximation of $A^{-1}$ then an iteration based on (2.4) can be expected to converge since then $I - RA$ will have a small spectral radius.

Therefore, from (2.4) we derive the following iteration, where we already use interval arithmetic and intervals $[y]_k$ for $y$:

$$[y]_{k+1} = R\diamondsuit(b - A\tilde{x}) + \diamondsuit(I - RA)[y]_k \tag{2.5}$$

or

$$[y]_{k+1} = F([y]_k) \tag{2.6}$$

where $F$ is the interval extension of $f$.

Here $\diamondsuit$ means that the succeeding operations have to be executed exactly and the result is rounded to an enclosing interval (-vector or -matrix). Since in the computation of the defect $b - A\tilde{x}$ and of the iteration matrix $I - RA$ serious cancellations of leading digits must be expected these should be computed using the exact scalar product, i.e. each component is computed exactly and then rounded to a machine interval. For this purpose the scalar product expressions of PASCAL-XSC will be used extensively in the implementations. With $z := R\diamondsuit(b - A\tilde{x})$ and $C := \diamondsuit(I - RA)$ now (2.5) can be written as:

$$[y]_{k+1} = z + C[y]_k \ .$$

In order to prove the existence of a solution of (2.2) and thus of (2.1), we use a fixed point theorem, i.e. Brouwer's fixed point theorem, which applies as soon as we have at some iteration index $k + 1$ an inclusion property of the form

$$[y]_{k+1} = F([y]_k) \subset [y]_k^\circ \tag{2.7}$$

where $[y]_k^\circ$ means the interior of $[y]_k$. If this *inclusion test* (2.7) holds, then the iteration function $f$ maps $[y]_k$ into itself and from Brouwers fixed point theorem it follows that $f$ has a fixed point $y^*$ which is contained in $[y]_k$ and thus even in $[y]_{k+1}$. The requirement that $[y]_k$ is mapped into its interior, makes shure, in addition, that this fixed point is also unique, i.e. (2.2) has a unique solution $y^*$ and thus (2.1) also has a unique solution $x^* = \tilde{x} + y^*$.

**Remark:**

According to [285] the inclusion test (2.7), when satisfied, implies that the spectral radius of $C$ (and even that of $|C|$, which is the matrix of absolute values of $C$) is less then 1 which ensures the convergence of the iteration (also in the interval case). Furthermore, this implies also the nonsingularity of $R$ and of $A$ and thus the uniqueness of the fixed point.

A problem which still remains is, that we do not know if we can succeed in achieving condition (2.7). E.g. in the trivial case of $n = 1$ with $a_{11} = 0.1, b = 0$ and $\tilde{x} = 1$ the iteration will converge to the unique solution $x^* = 0$ but will do this monotonically decreasing and (2.7) will never be satisfied.

To force (2.7) we therefore introduce the so called $\epsilon$-*inflation* which blows up the intervals somewhat, in order to "catch" a nearby fixed point. For a real interval $[w]$ we denote this with the functional notation $\mathrm{blow}([w], \epsilon)$ where

$$\mathrm{blow}([w], \epsilon) := \begin{cases} (1+\epsilon)[w] - \epsilon[w] & \text{, if } \mathrm{diam}([w]) > 0, \\ [\mathrm{pred}(w), \mathrm{succ}(w)] & \text{, if } \mathrm{diam}([w]) = 0 \end{cases} \tag{2.8}$$

where $\mathrm{diam}([w])$ is the diameter of the interval ($\mathrm{diam}([w]) = \overline{w} - \underline{w}$) and in the case $\mathrm{diam}([w]) = 0$, $[w] = w$ is assumed to be a floating point number and $\mathrm{pred}(w)$, $\mathrm{succ}(w)$ are its predecessor and successor in the floating point screen. Similarly, we use the $\epsilon$-inflation $\mathrm{blow}(\cdot)$ also for interval vectors and matrices, where it is applied componentwise.

It can be shown, e.g. [289] that (2.7) will always be satisfied after a finite number of iteration steps, whenever the absolute value $|C|$ of iteration matrix $C$ has spectral radius less than 1.

Up to this point we did not yet say how we compute our approximate solution $\tilde{x}$ and the approximate inverse $R$. In principle there is no special requirement about these quantities, we could even just guess them. However, the results of the enclosure algorithm will of course depend on the quality of the approximations.

We now sketch the method we use in our PASCAL-XSC program for the computation of $R$ and $\tilde{x}$.

To begin with, we do not use a special algorithm for the computation of the approximate solution, since we must compute an approximate inverse $R \approx A^{-1}$ anyway. Thus we also have immediately an approximate solution $\tilde{x} := Rb$.

However, the quality of this approximation is often not sufficient for the interval iteration to converge fast. Therefore, we first improve this approximation by use of an iterated defect correction:

$$\tilde{x}_{k+1} = \tilde{x}_k + R(b - A\tilde{x}_k) \tag{2.9}$$

using floating point arithmetic only and the exact scalar product for the defect $b - A\tilde{x}_k$. Improving the approximation in floating point first is much cheaper than computing many interval iterations later.

For the computation of the approximate inverse $R$ we use the Gauss-Jordan algorithm with column pivoting, which can be found in many numerical text books, e.g. [309]. We do not repeat the algorithm here since it is very standard (and it is listed as PASCAL-XSC code in Section 2.1.5 anyway). However, we explain a minor change in the algorithm which was included in order to make the algorithm

more robust in the case of almost singular matrices. This modification concerns the elimination steps of the Gauss-Jordan algorithm which may produce exact zeros on the computer because of rounding errors. Later in the computation, when a pivot element is to be searched for, it could be the case that no pivot can be found since all candidates are exact zeros on the machine, thus causing a breakdown of the Gauss-Jordan algorithm. Therefore we replace any exact zero value which was produced in an elimination step by a nonzero value in the order of magnitude of the roundoff error, i.e. we replace the result of $a - a = 0$ by $\epsilon a$ where $\epsilon$ is the relative machine precision. This modification forced the Gauss-Jordan algorithm to execute completely for any non singular matrix (and also many singular matrices) and, additionally, now the failure of finding a pivot element also means that the zeros have been already in the input matrix, which therefore must surely be singular.

In very ill conditioned cases the quality of $R$ computed this way will not be sufficient, i.e. the spectral radius of $|C|$ will not be less then 1 and therefore the inclusion test will never be satisfied. In this case we stop the interval iterations after a maximal number of iterations ( 10, say ) and recompute the approximate inverse in higher precision. The method how we do this goes back to Rump, [280], why we will call it Rump's device.

Assume we have an approximate inverse $R$ (as we do from the Gauss-Jordan algorithm), then even if $A$ is very ill conditioned, the matrix $RA$ is ususally very much better conditioned than $A$ is. Now the simple relation

$$A^{-1} = (RA)^{-1}R \tag{2.10}$$

suggests that we compute another approximate inverse $S$ of $RA$ and take the product of $S$ and $R$ as a better approximation of $A^{-1}$. Since we can compute this product exactly with the aid of the exact scalar product in the long accumulator, it is also easy to approximate it by the sum of two matrices $R_1$ and $R_2$.

Summarizing, we can compute an approximate inverse $R_1 + R_2$ of double length (stored in two real floating point matrices $R_1, R_2$) by the following steps:

1. compute an approximate inverse $R$ of $A$ with Gauss-Jordan.
2. compute $RA$.
3. compute an approximate inverse $S$ of $RA$ with Gauss-Jordan.
4. compute $SR$ in the long accumulator, and store it as sum of two floating point matrices $R_1$ and $R_2$.

Now that we have an approximate inverse $R := R_1 + R_2$ of double length, we can execute the algorithm described above with this $R$ by using the exact scalar product whenever $R = R_1 + R_2$ is used in the algorithm.

The overall strategy of our method finally can be summarized in two steps:

Part I compute an approximate inverse $R$ of single length and execute the enclosure algorithm. If this fails then goto

Part II improve the approximate inverse by Rump's device and execute the enclosure algorithm with the double length approximate inverse $R = R_1 + R_2$.

Now that we have treated the case of one linear equation with one right hand side $b$ we turn to the inversion of a matrix $A$. The inverse $X = A^{-1}$ is obviously the solution of the matrix-equation $AX = I$ with the $n \times n$ identity matrix on the right hand side. This equation can of course be solved column wise, thus obtaining the columns of $X = A^{-1}$ successively.

For the $n$ individual matrix-vector equations which have to be solved we use the algorithm just presented. In order to keep the computational overhead small we can make use of some simple observations which help us to avoid the recomputation of intermediate quantities in the algorithm: Since all $n$ equations have the same coefficient matrix $A$ it would be a big waste of computation time to recompute the approximate inverse $R$ and the iteration matrix $C = \diamondsuit(I - RA)$ for each of the $n$ matrix-vector equations.

Rather, we will implement the algorithm for the square case (s) in such a way, that the approximate inverse $R$ ( or $R_1, R_2$ if a double length inverse was needed ) as well as its residual matrix $C = \diamondsuit(I - RA)$ ( or $C = \diamondsuit(I - R_1A - R_2A)$ ) will be saved after the first computation and will be reused in the solution of the following equations.

In the PASCAL-XSC code the procedure which computes solutions of the square matrix-vector equation (i.e. the local procedure `LSS`) must communicate with its calling procedures for matrix-equations which quantities of the algorithm have already been computed ( $R$, $R_1$, $R_2$, $\diamondsuit(I - RA)$ and $\diamondsuit(I - R_1A - R_2A)$ ) and can be reused in a future call. For this communication a flag (named `FLAGS`) is used in the PASCAL-XSC program code in Section 2.1.5 which helps to avoid these unnecessary recomputations.

Next, we consider the cases of over- and of under-determined systems. (For more details on the theory see, e.g. [309]). In both cases we assume the $m \times n$-matrix $A$ to have full rank, i.e. in the over-determined case ( case (o), $m \geq n$ ) $A$ has rank $n$ and in the under-determined case ( case (u), $m \leq n$ ) $A$ has rank $m$. Here $x$ is an $n$-vector and $b$ is an $m$-vector.

In case(o) the system (2.1) has no solution in general. Therefore, we are rather interested in a vector $x$ which minimizes the Euclidian norm of the residual vector $r = b - Ax$, or, equivalently, the square of this norm, i.e. we seek the solution of the linear least squares problem:

$$\|Ax - b\|_2^2 = min \ .$$

It is well known (e.g. [309], [308]) that such an $x$ is uniquely determined (if $A$ has full rank) and that it is the solution of the so called system of *normal equations*

$$A^H Ax = A^H b \tag{2.11}$$

where $A^H$ is the Hermitian matrix of $A$, i.e. the transposed matrix in the real case.

We could now go ahead, compute $A^H A$ and $A^H b$ and solve the resulting square $n \times n$ system by use of the just previously presented method. However, as is well known, $A^H A$ has usually very bad condition and, moreover, on the computer it can only be obtained with roundoff errors or as an interval matrix which makes the solution of this system difficult.

Instead, we follow the suggestion of [285] and rewrite (2.11) as a larger square $(n+m) \times (n+m)$-system, which can be solved by the previous method to very high accuracy (but also with much higher computational effort if $m >> n$).

Introducing a new $m$-vector $y = Ax - b$ we immediately obtain $A^H y = 0$ from (2.11). We write these two equations in block form

$$\begin{pmatrix} A & -I \\ 0 & A^H \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix} \tag{2.12}$$

which is a square $(n+m) \times (n+m)$ system ( $I$ is the $m \times m$ identity matrix here). This system has much better condition than the original normal equations.

Now it is straight forward to solve (2.12) by the method for square systems. The $x$-part of the resulting enclosure then is an enclosure for the solution $x$ of the normal equations (2.11).

In a very similar way we also proceed in the case of under-determined systems. Here, the system (2.1) usually has infinitely many solutions and we are interested in the vector $y$ among these solutions $x$ which has minimal Euclidian norm. This vector can be determined as $y = A^H x$, where $x$ is the solution of $AA^H x = b$. Again we write these two equations in block form

$$\begin{pmatrix} A^H & -I \\ 0 & A \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 0 \\ b \end{pmatrix} \tag{2.13}$$

which again is a square $(n+m) \times (n+m)$ system (here $I$ is the $n \times n$ identity matrix).

Again, we solve this system (2.13) by use of the method for square systems. The $y$-part of the resulting enclosure then yields an enclosure for the solution of our problem.

Finally we treat the two cases (O) and (U), i.e. the computation of the Moore-Penrose pseudo inverse $A^+$ of $A$ in the over- and under-determined cases (here we also assume $A$ to have full rank).

In case (O) the $n \times m$-matrix $A^+$ ( $m \geq n$ ) is given by (see e.g. [309], [308]).

$$A^+ = (A^H A)^{-1} A^H \tag{2.14}$$

or, equivalently, by the solution $Y = A^+$ of the matrix equation $A^H AY = A^H$. Introducing the $m \times m$-matrix $X = AY - I$ we see that $A^H X = 0$ and, as previously, we can write these two equations in block form:

$$\begin{pmatrix} A & -I \\ 0 & A^H \end{pmatrix} \cdot \begin{pmatrix} Y \\ X \end{pmatrix} = \begin{pmatrix} I \\ 0 \end{pmatrix} \tag{2.15}$$

where both identity matrices are $m \times m$.

Solving this equation column-wise with the algorithm for square matrices we get an enclosure for the pseudo inverse $A^+$ by extracting the $Y$-block from the computed enclosure.

Since the pseudo inverse has the property $(A^+)^H = (A^H)^+$ it follows from (2.14) that in case (U) ( $m \leq n$) we have

$$A^+ = A^H(AA^H)^{-1}$$

or, equivalently, $A^+$ is the solution $Y = A^+$ of $YAA^H = A^H$. With the $n \times n$-matrix $X = YA - I$ we see that $XA^H = 0$. Taking the hermitian in the two latter equations we can again write these in a block form:

$$\begin{pmatrix} A^H & -I \\ 0 & A \end{pmatrix} \cdot \begin{pmatrix} Y^H \\ X^H \end{pmatrix} = \begin{pmatrix} I \\ 0 \end{pmatrix} \tag{2.16}$$

with the identity matrices being $n \times n$.

Solving this equation column-wise with the algorithm for square matrices we get an enclosure for the pseudo inverse $A^+$ by extracting the $Y^H$-block from the computed enclosure and taking its hermitian matrix as the result.

**Remark:**

We should stress that the alogrithms which were presented here for the cases (o), (u), (O) and (U) generally deliver very narrow bounds for the solution, but that they are computationally very expensive, at least in the case where $|m - n|$ is large since the solution is always computed by use of a system of dimension $n + m$. There are other methods which can enclose the solution more efficiently (though perhaps less accurate), see Section 2.1.7. The reasons for the presentation of our methods are their high accuracy and that they are straight forward and can be implemented in PASCAL-XSC in some 10-20 lines of code.

According to a remark in [285] the number of operations can be reduced substantially in our algorithms for the cases (o), (u), (O) and (U) if we carefully observe the special structure of the block coeffient matrices $B$ and compute only those elements of the approximate inverse $R$ and its residual matrix $I - RB$ which are actually needed.

### 2.1.3 Algorithms

According to Section 2.1.2 we can outline the following algorithms in a pseudo Pascal notation.

**Algorithm 2.1:** Solution of problem (s): {procedure}

{Compute enclosure for solution of square linear System $Ax = b$}

Part I (approximate inverse of single length)

I.1 compute an approximate inverse $R$ of $A$ (e.g. using Gauss-Jordan algorithm)

I.2 compute an approximation $\tilde{x} := Rb$ of $x$
improve $\tilde{x}$ by an iterated defect correction :
**repeat**
$\tilde{x} := \tilde{x} + R(b - A\tilde{x})$
**until** $\tilde{x}$ accurate enough or max. iteration count exceeded

I.3 compute enclosures for the residuum:
$Z := R\diamondsuit(b - A\tilde{x})$
and for the iteration matrix:
$C := \diamondsuit(I - RA)$

I.4 interval iteration
$Y := Z$
**repeat**
$Y_A := \text{blow}(Y, \epsilon)$ {$\epsilon$ - inflation }
$Y := Z + C \cdot Y_A$
**until** $Y \subset \text{int}(Y_A)$ or max. iteration count exceeded

I.5 **if** $Y \subset \text{int}(Y_A)$ **then**
a unique solution $x$ exists and $x \in \tilde{x} + Y$
**else**
**if** in Part I **then**
Part I failed, goto Part II with $R_1 := R$
**else**
algorithm failed, matrix $A$ ill conditioned or singular

Part II (approximate inverse of double length)

II.1 (compute an approximate inverse $R := R_1 + R_2$ of $A$ as follows:)
$S := R_1 \cdot A$
compute an approximate inverse $S_1$ for $S$ (e.g. using Gauss-Jordan algorithm)
$S := S_1 \cdot R_1$
$R_2 := S_1 \cdot R_1 - S$
$R_1 := S$

II.2 goto step I.2 of Part I.

## Algorithm 2.2: Solution of problem (o): {procedure}

{Compute enclosure for solution of over-determined linear System $Ax = b$}

1. $A_{big} := \begin{pmatrix} A & -I \\ 0 & A^H \end{pmatrix} \in \mathbb{R}^{(n+m)\times(n+m)}$

$B_{big} := \begin{pmatrix} b \\ 0 \end{pmatrix} \in \mathbb{R}^{n+m}$

$Y_{big} := \begin{pmatrix} x \\ y \end{pmatrix} \in \mathbb{R}^{n+m}$

2. solve $A_{big}Y_{big} = B_{big}$ by use of Algorithm 2.2.1
3. block $x$ from the vector $Y_{big}$ is the wanted enclosure.

**Algorithm 2.3:** Solution of problem (u): {procedure}

{Compute enclosure for solution of under-determined linear System $Ax = b$}

1. $A_{big} := \begin{pmatrix} A^H & -I \\ 0 & A \end{pmatrix} \in I\!R^{(n+m)\times(n+m)}$

   $B_{big} := \begin{pmatrix} 0 \\ b \end{pmatrix} \in I\!R^{n+m}$

   $Y_{big} := \begin{pmatrix} x \\ y \end{pmatrix} \in I\!R^{n+m}$
2. solve $A_{big}Y_{big} = B_{big}$ by use of Algorithm 2.2.1
3. block $x$ from the vector $Y_{big}$ is the wanted enclosure.

**Algorithm 2.4:** Solution of problem (S): {procedure}

{Compute enclosure for the inverse of the square matrix $A$}

1. (solve $AX = I$ column wise)
   **for** $i := 1$ **to** $n$ **do**
   **begin**
   $b_i := e_i$ ( $= i$-th unit vector )
   solve $Ax_i = b_i$ by use of Algorithm 2.2.1
   **end**
2. $X = (x_1, \ldots, x_n)$ is the wanted enclosure.

**Algorithm 2.5:** Solution of problem (O): {procedure}

{Compute enclosure for the pseudo inverse of the $m \times n$ matrix $A, m > n$}

1. $A_{big} := \begin{pmatrix} A & -I \\ 0 & A^H \end{pmatrix} \in I\!R^{(n+m)\times(n+m)}$, $I \in I\!R^{m\times m}$

   $B_{big} := \begin{pmatrix} I \\ 0 \end{pmatrix} \in I\!R^{n+m\times m}$, $I \in I\!R^{m\times m}, 0 \in I\!R^{n\times m}$

   $Y_{big} := \begin{pmatrix} X \\ Y \end{pmatrix} \in I\!R^{n+m\times m}$, $X \in I\!R^{m\times m}, Y \in I\!R^{n\times m}$
2. solve $A_{big}Y_{big} = B_{big}$ by use of Algorithm 2.2.4
3. block $X$ from the matrix $Y_{big}$ is the wanted enclosure.

**Algorithm 2.6:** Solution of problem (U): {procedure}

{Compute enclosure for the pseudo inverse of the $m \times n$ matrix $A, m < n$}

1. $A_{big} := \begin{pmatrix} A^H & -I \\ 0 & A \end{pmatrix} \in \mathbb{R}^{(n+m)\times(n+m)}$, $I \in \mathbb{R}^{m\times m}$

   $B_{big} := \begin{pmatrix} I \\ 0 \end{pmatrix} \in \mathbb{R}^{n+m\times n}$, $I \in \mathbb{R}^{n\times n}, 0 \in \mathbb{R}^{m\times n}$

   $Y_{big} := \begin{pmatrix} Y^H \\ X^H \end{pmatrix} \in \mathbb{R}^{n+m\times n}$, $X \in \mathbb{R}^{n\times n}, Y \in \mathbb{R}^{n\times m}$
2. solve $A_{big}Y_{big} = B_{big}$ by use of Algorithm 2.2.4
3. block $X$ from the matrix $Y_{big}$ is the wanted enclosure.

### 2.1.4 Applicability of the Algorithms

The algorithms presented in Section 2.1.4 can be applied to any system of linear equations which can be stored in the floating point system on the computer. They will, in general, succeed in finding and enclosing a solution or, if they do not succeed will tell the user so. In the latter case the user will know that the problem is very ill conditioned or that the matrix $A$ is singular.

In the following implementation in PASCAL-XSC there is the chance that if the input data contains large numbers or if the inverse of $A$ or the solution itself contain large numbers there may occur an overflow in which case the algorithms break down uncontrolled. In practical applications this has never been observed, however. This could also be avoided by including the floating point exception handling which PASCAL-XSC offers for IEEE floating point arithmetic.

If the problem contains interval data in the matrix $A$ or in the right hand side $b$ then the algorithms can be applied, too, however, the exact solution set is usually overestimated by the enclosure which is computed by the algorithm. Usually this overestimation becomes larger as the diameter of the input interval increases. Also for certain classes of matrices for which the optimal interval hull of the solution set can be computed (e.g. interval M-matrices) this algorithm will usually overestimate the solution set. This overestimation can be estimated by use of certain quantities appearing in the algorithm. We will not discuss this here, however. For details see e.g. [288] and [91].

### 2.1.5 PASCAL-XSC Program Code

The PASCAL-XSC program which is given here is written for the case of real input data, i.e. $A$ is of type *rmatrix* and $b$ is of type *rvector*. However, because of the very clear structure of PASCAL-XSC it is easy to transform this program code to make use of the other data types *interval, complex* and *complex interval*. The changes in the program are mainly changes of the data type of certain variables and functions. We will indicate the necessary changes at the end of this section.

The following module `lss_aprx` contains the procedure `MINV` which computes an approximate inverse of the input matrix `A` of type *rmatrix* by use of the Gauss-Jordan algorithm (see e.g. [309]). The parameter `A` is for input and output. The second parameter `err` indicates if an approximate inverse could be computed (`err=0`) or if the computation failed (`err=1`).

There is, however, one trick included in this algorithm: in order to be able to complete the algorithm even for ill conditioned matrices we avoid to compute matrix elements which are exactly zero in the elimination step. For ill conditioned matrices these elements could appear later as pivot elements, thus forcing the computations to break down. If the elimination step would yield an element `a[l,k]` which is rounded to an exact zero we rather replace it by `eps*a[l,k]` with the old value of `a[l,k]` and an `eps` close to the relative machine precision. If we then still find a zero pivot element, then it must have been in the input matrix already which means that the input matrix was actually singular. (This is, however, only almost true, since we did not consider the possibility of underflow in the multiplication `eps*a[l,k]`).

The reason why the array index computations look somewhat complicated is that we do not assume that the matrix `A` has the same index ranges in both dimensions, it only has to be square. E.g. if `A` is $10 \times 10$ the first index migth run from 0 to 9 whereas the second index could run from $-5$ to 4.

```

        j:= au2+i-au1;
        r:= RVECTOR(a[*,j]); a[*,j]:= a[*,l]; a[*,l]:= r;
     END;
  END;
  err:= ORD( NOT ok );
END {*** MINV ***};

BEGIN
  { module body empty }
END.
```

The following module `lss.p` contains the functions and procedures which solve the problems (s), (o), (u), (S), (O) and (U) stated in Section 2.1.1 for a coefficient matrix of type *rmatrix* and a right hand side of type *rvector*.

There are only two global procedures contained in `lss` – `LSS` and `INV` – which can be called from other modules than `lss`. `LSS` accepts linear systems of the form (2.1) with any matrix, checks the dimensions of the coefficient matrix `A` and calls other procedures which handle the square or rectangular cases. Similarly, `INV` checks its parameter `A` and calls other routines for the square or rectangular cases.

The procedures and functions have the following meanings (in order of their static appearance) :

`REL`:

Computes the maximum relative error of the components of the two parameter vectors `A` and `B`. It is used in the stopping criterion of the real defect iteration for an improvement of the real approximations in the procedures `USE_SINGLE_R` and `USE_DOUBLE_R` (both local to the first procedure `LSS`).

`TOO_BAD`:

Checks the accuracy of the parameter `A`. If at least one component is larger than $[-10^{20}, 10^{20}]$ then the function yields `TRUE` else `FALSE`. It is used to abort the interval iteration if it seems to diverge (again in `USE_SINGLE_R` and `USE_DOUBLE_R`).

`GUESS_ZEROES`:

Tries to guess if a component of the solution is equal to zero. This is assumed to be the case if this component (i) has changed sign in the last two successive iterations or if (ii) it has decreased by more than a factor of $10^{-6}$ from the previous iterate to the last iterate and if it is less in magnitude than $10^{-6}$ times the maximum magnitude of all other components of the last iterate. Replacing such components by zero often improves the enclosures by many orders of magnitudes. On the other hand, if the guess was wrong, then zero is still a good approximation such that the enclosures will stay good.

`LSS`:

This is the central procedure of the module. It implements the algorithm for a square system $Ax = b$ by first trying an iteration with an approximate inverse of single length (procedure `USE_SINGLE_R`) and in case of no success with an approximate inverse of double length (procedure `USE_DOUBLE_R`). Input parameters are `A` and `b`. Output parameters are `Y` and `errcode`. The other parameters are for input as well as for output. Since `LSS` is called by the procedures for matrix inversion several times, the computation of the approximate inverses (`R1,R2`) and the iteration matrix `C` is controlled by the parameter `FLAGS` which indicates in successive calls to `LSS` which of the matrices `R1,R2,C` have already been computed in order to avoid unnecessary and costly recomputation of these quantities. For details see the comment at the beginning of `LSS`.

`USE_SINGLE_R`: (local to `LSS`)

This procedure implements the algorithm by using an approximate inverse `R1` of single length which is computed by the procedure `MINV`.

After the computation of `R1` we compute an approximate solution `x1:= R1*b` and execute a defect iteration in floating point arithmetic in order to improve this approximation `x1`. It is very essential here to use scalar product expressions since the computation of the residuum `b-A*x0` must necessarily suffer from severe cancellation. This iteration is stopped if (i) the maximal relative error `p` is less than `delta` ($= 10^{-15}$) or if the relativ error decreases very slowly only, such that `p` becomes larger than `bound` which is multiplied by a factor of $\approx \sqrt{0.1}$ in each iteration starting after the 5th iteration. This means roughly that after the 5th iteration we expect the approximation to gain at least one decimal digit each two iterations,

otherwise we stop the iteration process.

Subsequent to this floating point iteration we try to guess if some of the solution components are exactly zero by calling procedure `GUESS_ZEROES`.

Next, we compute an enclosure of the residuum `b-A*x1` in double length (real vector `y0` plus interval vector `Y1`) in order to get still high accuracy for the product with `R1`. Here the repeated computation of `A*x1` inside the `#`-expressions could be avoided if these expressions were computed component wise by use of a variable of type *dotprecision*. However, since these computations are cheap as compared to the rest of the algorithm we prefer this version which is much easier to read.

This residuum is checked if it is exactly the zero vector: in this case `x1` is an exact solution of the system. Thus we can stop the algorithm at this point and need not continue with the costly interval iteration (However, stopping here means that we have an exact solution, but that we do not know if it is unique. If we need uniqueness we have to continue with the interval iteration.)

Finally the iteration matrix `C` is computed (again with scalar product expression because of cancellations) and the interval iteration for the defect `Y1` of the approximation `x1` is executed. Beginning with the 5th iteration the inflation parameter `eps` is multiplied by 5 in each iteration in order to accelerate convergence or divergence. This iteration is stopped (i) if it was successful, i.e. if an iterate `Y1` is contained in its predecessor `YA`, (ii) after a maximum iteration count of 10, or (iii) if the accuracy becomes too bad (indicating divergence).

In the case of a successful interval iteration the resulting enclosure `x1+Y1` of the solution is returned in `Y` and the error code is set to zero.

`USE_DOUBE_R`: (local to `LSS`)

This procedure implements the algorithm by using an approximate inverse `R1+R2` of double length (i.e. `R1` and `R2` are of type *rmatrix* each), which is computed by the use of Rump's device as explained in Section 2.1.2.

The following steps are completely analogous to those in `USE_SINGLE_R` except that wherever the approximate inverse appears the double length representation has to be used. Note that in the floating point defect iteration the iterates are computed in double length also (`x1+x0`) but subsequently only the high value part `x1` is used. Also, note that `y0` is an auxiliary variable in the floating point iteration.

Here again we make use of a repeated computation of `A*x1` only to make the program easier to read. Similarly, the two assignments `D := R2*R1;` and `R2:= #*( R2*R1 - D );` near the beginning of `USE_DOUBE_R` cause repeated computation of `R2*R1`. However, the costs for this are additional $n^3$ operations. If we do not want this higher overhead, then we have to replace these two assignments by the following double loop:

```
FOR i:= LB(A) to UB(A) do
FOR j:= LB(A) to UB(A) do
BEGIN
   dot    := #( R2[i]*RVECTOR(R1[*,j]) );
   D[i,j] := #*( dot );
   R2[i,j]:= #*( dot - D[i,j] );
```

```
END;
```

Furthermore, in this case we have to add the declarations

```
VAR dot : DOTPRECISION;
    i,j : INTEGER;
```

in the declaration part of USE_DOUBE_R.

SQUARE_LSS:
This procedure treats the case of a square coefficient matrix. The trivial case of a $1 \times 1$ matrix is solved explicitly, whereas for $n > 1$ the storage for R1,R2,C and FLAGS is used to call the procedure LSS described above.

OVER_LSS, UNDER_LSS:
These procedure handles the over- and under-determined case respectively of a linear system. Both procedures allocate variables BIG_A,BIG_B and BIG_Y for the augmented problems and initialize BIG_A and BIG_B appropriately according to Section 2.1.2. Then this augmented square system is solved by a call to procedure SQUARE_LSS. Finally those components of the big solution vector are extracted which are needed for the solution of the original problem.

LSS:
This procedure is the only global entry for the solution of linear systems in this module lss. It first checks the parameter for consistent dimensions, then decides which case (s), (o) or (u) has to be treated and calls the appropriate procedure SQUARE_LSS, OVER_LSS or UNDER_LSS.

SQUARE_INV, OVER_INV, UNDER_INV, INV:
These procedures compute enclosures for the inverse matrices (or the pseudo inverse) and are completely analogous to those for linear systems. As mentioned above, INV is the only global procedure for this purpose and calls the other ones appropriately. The only difference to the corresponding -LSS procedures is that they compute the inverse column wise and therefore have to call the local linear system solving procedure LSS several times. Therefore, the matrices R1,R2 and C are defined locally in these procedures and their computation is controlled by the variable FLAG as discussed previously (see local procedure LSS). Note that in procedure SQUARE_INV the resulting columns of the inverse matrix Y are first written into the rows of the result matrix. Therefore, Y has to be transposed at the end of the procedure.

```

Concluding this section we want to indicate which changes have to be done in the preceding PASCAL-XSC program code in order to get programs that treat the cases of *interval, complex* and *complex interval* input data.

First we consider the case of interval data, i.e. the input matrix $A$ is an interval matrix and the right hand side $b$ is an interval vector.

We construct a new module `ilss` from the above module `lss` by applying the changes which we describe now.

This are the changes in the first (local) procedure `LSS`:

- In the procedure head make `A` an `IMATRIX` and `b` an `IVECTOR`.
- In the declaration part add variables `AM` of type `RMATRIX` and `bm` of type `RVECTOR` which will be used to hold the midpoints of `A` and `b`.
- At the beginning of the procedure body add the statements `AM:= MID(A); bm:= MID(b); .`
- In the local procedure `USE_SINGLE_R` replace in each of the three statements `R1:= A; x1:= R1*b;` and `x1:= #*( b - A*x0 );` the variables `A` by `AM` and `b` by `bm`.
- Also in `USE_SINGLE_R` replace `y0:= #*( b - A*x1 );` by `y0:= MID( ##( b - A*x1 ) );`

- In the local procedure `USE_DOUBLE_R` replace in each of the four statements `R2:= R1*A; x1:= #*( R1*b + R2*b ); x0:= #*( R1*b + R2*b - x1 );` and `y0:= #*( b - A*x1 - A*x0 );` the variables `A` by `AM` and `b` by `bm`.

- Also in `USE_DOUBLE_R` replace `y0:= #*( b - A*x1 );` by `y0:= MID( ##( b - A*x1 ) );`

The other procedures in the module must be modified as follows:

- In the heads of the procedures `SQUARE_LSS`, `OVER_LSS`, `UNDER_LSS`, `LSS`, `SQUARE_INV`, `OVER_INV`, `UNDER_INV` and `INV` make `A` an `IMATRIX` and `b` an `IVECTOR`.

- In `SQUARE_LSS` and in `SQUARE_INV` replace the test `A[LB(A,1),LB(A,2)]=0.0` by the test `0.0 IN A[LB(A,1),LB(A,2)]` and delete the conversion function `INTVAL` in the special case `dim=1` in both procedures.

- In the procedures `OVER_LSS`, `UNDER_LSS`, `OVER_INV` and `UNDER_INV` change the types of the local variables `BIG_A` and `BIG_B` to the types `IMATRIX` and `IVECTOR`.

- In procedure `SQUARE_INV` change the type of the local variable `b` from `RVECTOR` to `IVECTOR`.

Next, we turn to the case of a complex input matrix $A$ and a complex input vector $b$. In this case we also have to modify the procedure `MINV` such that an approximate inverse of a complex matrix can be computed. We write a new module `clssaprx` by copying `lss_aprx` with the following modifications:

- Instead of using module `mv_ari` we use modules `c_ari,mvc_ari` for complex and complex matrix/vector arithmetic.

- The types of the parameter `A` of `MINV` and the local variables `r` and `h` must be replaced by their equivalent complex types `CMATRIX`, `CVECTOR` and `COMPLEX`.

- The two occurrences of the conversion function `RVECTOR` in the body of `MINV` must be replaced by the conversion function `CVECTOR`.

A module `clss` will now be constructed as a copy of module `lss` by applying the following changes:

- Replace the `USE` line by `USE i_ari,c_ari,ci_ari,mv_ari,mvc_ari, mvci_ari,clssaprx;`

- Replace *all* occurrences of `RMATRIX` by `CMATRIX`, `RVECTOR` by `CVECTOR`, `IMATRIX` by `CIMATRIX` and `IVECTOR` by `CIVECTOR` throughout the module.

- In function `REL` change the type of `ai,bi` from `REAL` to `COMPLEX` and delete the test `ai*bi <= 0.0` without replacement.

- In function `TOO_BAD` replace statement
  ```
  bad:= bad OR (A[i].INF<-abort) AND (A[i].SUP>abort);
  ```
  by
  ```
  bad:= bad OR (A[i].RE.INF<-abort) AND (A[i].RE.SUP>abort)
            OR (A[i].IM.INF<-abort) AND (A[i].IM.SUP>abort);
  ```

- In function `GUESS_ZEROES` delete the test `x0[i]*x1[i]<0.0` without replacement.

- In the procedures `OVER_LSS`, `UNDER_LSS`, `OVER_INV` and `UNDER_INV` we must replace all function calls to the function `TRANSP` by calls to the function `HERM`. Additionally, in `UNDER_INV` the statement `Y[LB(Y,1)+i-1]:= BIG_Y[1..m];` must be replaced by `Y[LB(Y,1)+i-1]:= CONJ( BIG_Y[1..m] );`.

Finally a new module `cilss` can be constructed from the module `ilss` by applying exactly the same changes as for the conversion from `lss` to `clss`.

### 2.1.6 Test Results

A very well known set of ill conditioned test matrices for linear system solvers are the $n \times n$ Hilbert matrices $H_n := (\frac{1}{i+j-1})$. As a test problem we report the results of our program for the linear systems $H_n x = e_1$ where $e_1$ is the first canonical unit vector. Thus the solution $x$ is the first column of the inverse $H_n^{-1}$ of the Hilbert matrix $H_n$. We give results for the cases $n = 10$ and $n = 20$. Since the elements of these matrices are rational numbers which can not be stored exactly in floating point, we do not solve the given problems directly but rather we multiply the system by the least common multiple $lcm_n$ of all denominators in $H_n$. Then the matrices will have integer entries which makes the problem exactly storable in IEEE floating point arithmetic. For $n = 10$ we have $lcm_{10} = 232792560$ and for $n = 20$ we have $lcm_{20} = 5342931457063200$.

For the system $(lcm_{10} H_{10})x = (lcm_{10} e_1)$ the program computes the result:

| | |
|---|---|
| $x_1$ | 1.000000000000000E+002 |
| $x_2$ | -4.950000000000000E+003 |
| $x_3$ | 7.920000000000000E+004 |
| $x_4$ | -6.006000000000000E+005 |
| $x_5$ | 2.522520000000000E+006 |
| $x_6$ | -6.306300000000000E+006 |
| $x_7$ | 9.609600000000000E+006 |
| $x_8$ | -8.751600000000000E+006 |
| $x_9$ | 4.375800000000000E+006 |
| $x_{10}$ | -9.237800000000000E+005 |

which is the exact solution of this ill conditioned system.

For the system $(lcm_{20}H_{20})x = (lcm_{20}e_1)$ the program computes the enclosures (here an obvious short notation for intervals is used):

| | |
|---|---|
| $x_1$ | $\frac{4.000000000000001}{3.999999999999999}E+002$ |
| $x_2$ | $-7.9\frac{79999999999998}{80000000000002}E+004$ |
| $x_3$ | $5.266\frac{800000000001}{799999999999}E+006$ |
| $x_4$ | $-1.71609\frac{8999999999}{9000000001}E+008$ |
| $x_5$ | $3.2949100\frac{80000001}{79999999}E+009$ |
| $x_6$ | $-4.118637\frac{599999999}{600000001}E+010$ |
| $x_7$ | $3.5694859\frac{20000001}{19999999}E+011$ |
| $x_8$ | $-2.23730278\frac{1999999}{2000001}E+012$ |
| $x_9$ | $1.044074631\frac{600001}{599999}E+013$ |
| $x_{10}$ | $-3.70066452\frac{59999}{60001}E+013$ |
| $x_{11}$ | $1.009272143\frac{80001}{79999}E+014$ |
| $x_{12}$ | $-2.133234304\frac{09999}{10001}E+014$ |
| $x_{13}$ | $3.500692191\frac{60001}{59999}E+014$ |
| $x_{14}$ | $-4.443186242\frac{79999}{80001}E+014$ |
| $x_{15}$ | $4.316238064\frac{2001}{1999}E+014$ |
| $x_{16}$ | $-3.147256922\frac{39999}{40001}E+014$ |
| $x_{17}$ | $1.666194841\frac{80001}{79999}E+014$ |
| $x_{18}$ | $-6.044040109\frac{799999}{800001}E+013$ |
| $x_{19}$ | $1.343120024\frac{400001}{399999}E+013$ |
| $x_{20}$ | $-1.378465288\frac{199999}{200001}E+012$ |

which is an extremely accurate enclosure for the exact solution. (The exact solution components are the integers within the computed intervals).

### 2.1.7 Notes and References

In the program the case $n = 2$ should of course be computed separately, as it is done for $n = 1$. This concerns the procedures `SQUARE_LSS` and `SQUARE_INV` in module lss as well as `MINV` in lss_aprx. We have omitted these cases to keep the procedures somewhat shorter. Even $n = 3$ might be worth to be programmed directly.

The form of the result of iterated defect correction in the algorithm

$$x \in \tilde{x} + [y]$$

is a special case of a so-called staggered correction format which has the more general form

$$x \in \sum_{i=1}^{k} x_i + [y]$$

where the sum of the $x_i$ is an approximation of $x$ and $[y]$ an enclosure of its error. Such a representation can easily be obtained by a modification of our algorithm in

such a way that several iterated defect correction steps are performed. The staggered correction format will be extensively discussed in Section 6.

If the algorithm is modified in the way that it produces output in staggered correction format then a further modification is almost trivial such that also input is possible in staggered format i.e. the coefficient matrix $A$ and the right hand side $b$ may be in staggered form. Then we have a verifying multi-precision linear system solver.

Such a linear system solver in staggered format can be applied to solve the least squares problem and compute the pseudo inverse in a different and cheaper way as we have done it in our program. For the least squares problem we proceed as follows (see [308]): In the case $m \geq n$ we compute $B := A^H A$ and $d := A^H b$ in double length (i.e. $B$ and $d$ have staggered format) and solve $Bx = d$ with the staggered linear system solver. In the case $m \leq n$ we compute $B := AA^H$ in double length and solve $Bx = b$ with the staggered linear system solver. Then, finally, $y = A^H x$ is the desired solution (which must be computed in double length).

The methods presented in this section were originally developed by S. Rump, [280], [285], some ideas go back to Wilkinson, [333].

In the meantime some newer methods exist which use $LU$-Factorization with backward error estimation for the solution of full triangular systems, [153]. These algorithms can be adapted to the condition of the system and use less computing time as ours in the case of well conditioned problems.

Also for symmetric matrices there exist special methods which give better results especially in the case of an interval matrix $A$ and which have somewhat less overhead.

For symmetric and positive definite matrices a variant of the Cholesky method has been investigated by [19].

Similarly for M-matrices and H-matrices different methods exist, e.g. the interval Gauss elimination can be applied in these cases. For details see [11], [13], [242].

Another wide area of methods are iterative methods which are not directly based on defect correction. See also [238], [239], [241].

Finally we note that our algorithm is not well suited for large systems which are sparse or which have banded structure since the approximate inverse $R$ will be in general a full matrix. Special methods for these cases are discussed in the next section.

## 2.2 Systems with Band Matrices

### 2.2.1 Introduction

For linear systems where the coeffient matrix $A$ has band structure the algorithm from Section 2.1 can be used without modification of course. However, since an approximate inverse $R$ is used there this would result in a large overhead of storage and computation time, especially if the bandwidth of $A$ is small compared with its dimension. To reduce this overhead, we will replace the approximate inverse by an approximate $LU$-decomposition of $A$ which needs memory of the same order of

magnitude only as $A$ itself. Then we will have to solve systems with triangular banded matrices (containing point data) in interval arithmetic. This seems to be a trivial task and several methods have been developed using such systems and simple forward and backward substitution in interval arithmetic, see e.g. [177], [178], [179], [78], [79], [295]. However, at this point there appears suddenly a very unpleasant effect which makes the computed intervals blow up very rapidly in many cases. This effect is known in literature as *wrapping effect* (see e.g. [247], [257]) and was recognized first in connection with the verified solution of ordinary initial value problems. However it is a common problem within interval arithmetic and may show up whenever computations in $\mathbb{IR}^n$, $n > 1$, are performed, e.g. if an interval vector is multiplied repeatedly by matrices or more general if a function $f : \mathbb{IR}^n \to \mathbb{IR}^n$ is applied repeatedly to an argument $x$, $x_n = f(f(\cdots f(f(x))\cdots))$. It should be noted that the wrapping effect is not related to roundoff errors or any other sources of errors in an algorithm (like truncation errors, discretization errors and the like) but it is introduced solely by interval arithmetic itself (though any additional errors may contribute to an increase of the wrapping effect).

Some simple examples illustrate this effect very drastically:

**Example 2.1:**
This example is the classical example for which the wrapping effect was discovered first. It comes from the solution of the initial value problem $u'' + u = 0, u(0) = u_0, u'(0) = u_1$, see [247], [207]. With the matrix

$$A_\phi := \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix}$$

consider the following simple recursion in $\mathbb{IR}^2$:

$$x_{n+1} = A_\phi x_n, \quad n \geq 0, \quad x_0 \in [x_0] := \epsilon \begin{pmatrix} [-1,1] \\ [-1,1] \end{pmatrix} \quad \epsilon > 0. \tag{2.17}$$

For each point vector $x_0 \in [x_0]$ we have obviously the solution

$$x_n = A_\phi^n x_0 = \begin{pmatrix} \cos n\phi & \sin n\phi \\ -\sin n\phi & \cos n\phi \end{pmatrix} x_0, \ n \geq 0 \tag{2.18}$$

i.e. the vector $x_n$ is constantly rotating around the origin by an angle $\phi$ each iteration. Thus the solution set $\{x_n | x_0 \in [x_0]\}$ is just the original square $[x_0]$ rotating constantly around the origin. Trivially this set remains bounded for all $n \geq 0$.

In contrast if we carry out the iteration (2.17) in interval arithmetic (with exact computations, no roundoff errors)

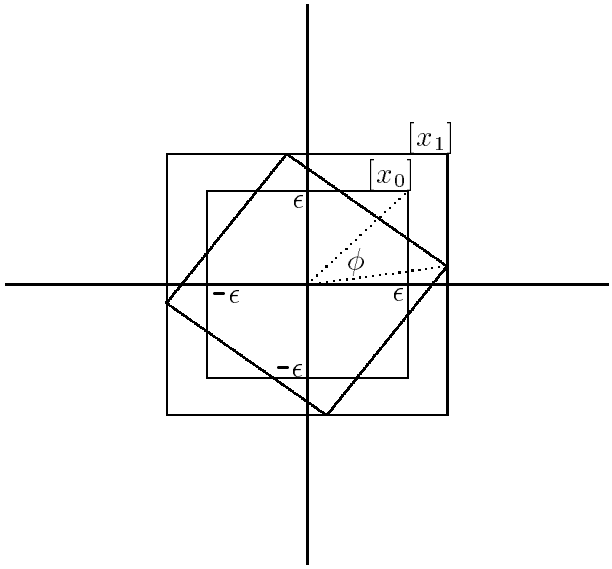
$$[x_{n+1}] = A_\phi [x_n] \tag{2.19}$$

where all operations are interval operations now, then we obtain

$$[x_1] \quad = \quad \begin{pmatrix} [-\epsilon,\epsilon]\cos\phi + [-\epsilon,\epsilon]\sin\phi \\ [-\epsilon,\epsilon]\sin\phi + [-\epsilon,\epsilon]\cos\phi \end{pmatrix} = \epsilon(|\sin\phi| + |\cos\phi|) \begin{pmatrix} [-1,1] \\ [-1,1] \end{pmatrix}$$

$$
\begin{aligned}
[x_2] &= \epsilon(|\sin\phi| + |\cos\phi|)^2 \begin{pmatrix} [-1,1] \\ [-1,1] \end{pmatrix} \\
&\vdots \\
[x_n] &= \epsilon(|\sin\phi| + |\cos\phi|)^n \begin{pmatrix} [-1,1] \\ [-1,1] \end{pmatrix} \quad .
\end{aligned}
$$

The interval vectors $[x_n]$ are of course enclosures for the bounded true solution sets $\{x_n | x_0 \in [x_0]\}$. However, since $|\sin\phi| + |\cos\phi| > 1$ for all $\phi \neq k\pi/2$ we see that the diameter of this enclosure diverges to $\infty$. This is the aforementioned wrapping effect which has a simple geometric explanation: the interval vector $[x_0]$ is rotated by an angle of $\phi$ around the origin and then enclosed ('wrapped') by the smallest possible interval vector $[x_1]$ whose diameter is $|\sin\phi| + |\cos\phi|$ times as large as that of $[x_0]$. The same process is repeated in each of the following iteration steps. We note that this wrapping occurs even though we use an optimal enclosure in each step. The following picture illustrates this geometric process.



This iteration can easily be rewritten as a system of linear equations

$$Ax = b \tag{2.20}$$

with a matrix $A$ which is lower triangular and banded. We write $A \in \mathbb{R}^{(2n+2)\times(2n+2)}$ and $x, b \in \mathbb{R}^{2n+2}$ in the following block notation with $2 \times 2$-blocks in $A$, $I$ being the $2 \times 2$-identity matrix, and 2-vectors in $x$ and $b$:

$$
\begin{aligned}
A &= \begin{pmatrix} I & & & \\ A & -I & & \\ & \ddots & \ddots & \\ & & A & -I \end{pmatrix} \\
x &= (x_0, x_1, \ldots, x_n)^T \\
b &= (x_0, 0, \ldots, 0)^T
\end{aligned}
$$

Obviously solving this block system by forward substitution in interval arithmetic is equivalent to the computation of the iteration in (2.19). Thus we have a first example that simple forward substitution in an interval setting can produce unacceptably large overestimations.

**Example 2.2:**
A similar example as the previous one, now with a full lower triangular matrix is as follows. Let $A$ be the $n \times n$-matrix

$$A = \begin{pmatrix} 1 & & & & & \\ 2 & 1 & & & & \\ 3 & 2 & 1 & & & \\ 4 & 3 & 2 & 1 & & \\ \vdots & \ddots & \ddots & \ddots & \ddots & \\ n & \cdots & 4 & 3 & 2 & 1 \end{pmatrix} .$$

The inverse $A^{-1}$ can easily be verified to be the banded lower triangular matrix

$$A = \begin{pmatrix} 1 & & & & \\ -2 & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \end{pmatrix} .$$

If we choose as right hand side the interval vector

$$[b] = \epsilon([0,1],[0,1],\ldots,[0,1])^T$$

then the optimal enclosure of the exact solution set $\{x = A^{-1}b | b \in [b]\}$ is

$$[x]_{opt} = \epsilon([0,1],[-2,1],[-2,2],\ldots,[-2,2])^T$$

which is identical to $[-2\epsilon, 2\epsilon]$ in all components but the first and second.

However, solving $Ax = [b]$ by forward substitution in interval arithmetic yields the following enclosures

$$x \in \epsilon \begin{pmatrix} [0,1] \\ [-2,1] \\ [-5,5] \\ [-17,17] \\ [-58,58] \\ [-198,198] \\ [-676,676] \\ [-2308,2308] \\ [-7880,7880] \\ [-26904,26904] \\ \vdots \end{pmatrix}$$

whose diameters are obviously diverging. This is an example where a blow up of the enclosing intervals occurs without having a nice and obvious geometric interpretation.

We note that also the system $By = [b]$ with the inverse matrix $B := A^{-1}$ as coefficient matrix shows a similar behaviour: the solution set $\{y = B^{-1}b = Ab | b \in [b]\}$ is unbounded here, but nevertheless the enclosures obtained by interval forward substitution still overestimate this set by an even far greater amount as can be easily checked. This system has also a great similarity with the following example.

**Example 2.3:**
The last example starts with a scalar, linear difference equation. The well-known Chebychev polynomials $T_n(x)$ can be defined by the second order recurrence relation

$$T_0(x) = 1, \quad T_1(x) = x, \quad T_{n+1}(x) - 2xT_n(x) + T_{n-1}(x) = 0 \ .$$

If we wish to compute an enclosure of $T_n(x)$ for some value $x_0$ and a high value of $n$ then we can use this difference equation and compute the desired value in interval arithetic. However, this computation is nothing else but interval forward substitution for the system

$$\begin{pmatrix} 1 & & & & \\ 0 & 1 & & & \\ 1 & -2x_0 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2x_0 & 1 \end{pmatrix} \begin{pmatrix} T_0(x_0) \\ T_1(x_0) \\ T_2(x_0) \\ \vdots \\ T_n(x_0) \end{pmatrix} = \begin{pmatrix} 1 \\ x_0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \ .$$

This is a system with point data only, however in interval floating-point arithmetic we will get sooner or later roundoff errors which introduce intervals with nonzero diameters. Then as in the last examples here also a very fast blow up of the enclosures will occur. If the argument $x_0$ is not a floating-point number, then such intervals will enter the computation right from the beginning. If we take e.g. $x_0 = 0.99$ then we obtain the following output from a short PASCAL-XSC program (IEEE double precision) for the values of $n$ and the enclosures for $T_n(0.99)$:

```
n                          T[n](0.99)

```

Of course the values of the Chebychev polynomials can be computed in a much easier way, since $T_n(x) = \cos(n \arccos x)$. This example should only demonstrate the difficulties that can arise with difference equations even as simple as this one. Nevertheless this example still is relevant since many other functions can be computed by use of certain difference equations (e.g. Bessel functions where the recursion $J_{n+1}(x) - \frac{2n}{x} J_n(x) + J_{n-1}(x) = 0$ is similarly sensitive to the wrapping effect).

These examples show clearly that it is important to find good methods for enclosing the solutions of triangular system of equations. Also it is obvious that difference equations and banded triangular systems are very closely related. Thus it can be expected that a method that works well with either one type should also work well with the other type of systems. This relationship between linear difference equations and linear systems with triangular matrix will be the basis for the method which we present in this Section for difference equations and for systems with banded matrices.

In Section 2.2.2 we will first treat the case of difference equations. We will demonstrate a method for first order vector difference equations (such as in Example 2.1) which reduces the wrapping effect to a large extent by enclosing the solution in suitably chosen coordinate systems. Scalar difference equations of higher order than one (as in Example 2.3) are then reformulated as linear first order matrix-vector difference equations. In this way the benefit of the reduction of the wrapping effect carries over to scalar difference equations of higher order also. Finally in Section 2.2.3 we will apply the same technique to linear systems with banded matrices (see Example 2.2) by rewriting them as linear difference equations and applying the methods of Section 2.2.2.

Other approaches to large systems – banded and sparse – can be found in [292]. An investigation of the wrapping effect within our context of linear systems is contained in [257].

## 2.2.2 Difference Equations

### 2.2.2.1 Theoretical Background

We start this section by discussing an enclosure method for first order vector difference equations of the following form

$$y_{i+1} = A_i y_i + d_i, \quad i \geq 0, \quad \text{with} \quad y_0 \quad \text{given.} \tag{2.21}$$

Here, the $y_i$ and $d_i$ are $m$-vectors and the $A_i$ are $m \times m$-matrices ($i \geq 0$).

This equation has an immediate geometric interpretation in $\mathbb{R}^m$ since it is an affine mapping of $y_i$ to $y_{i+1}$. From Example 2.1 we know that we may run into the wrapping effect if we compute (2.39) in interval arithmetic. However, here we know a geometric explanation of this effect and therefore can take counter-measures using this information. Assume that at some index $i$ of the iteration we have an interval vector $[y_i]$ as the result of (2.39) then $\{y_{i+1}|y_i \in [y_i]\}$ will be the affine image of $[y_i]$, i.e. this set will be a parallel-epiped. If we try to compute the enclosure as parallel-epipeds rather than as interval vectors then we can avoid the wrapping completely. Unfortunately this is true in theory only, since the roundoff errors on a computer bring back this effect again, see e.g. [257]. Nevertheless using parallel-epipeds is of great advantage also when computing in floating-point arithmetic.

A parallel-epiped can easily be represented on a computer by use of a (regular) basis matrix $B$ an interval vector $[z]$ and a point vector $\tilde{y}$. Then the point set

$$P := P(B, [z], \tilde{y}) := \{\tilde{y} + Bz | z \in [z]\} \tag{2.22}$$

is a parallel-epiped with one corner being $\tilde{y}$ and with edges parallel to the column vectors of $B$.

A somewhat simpler form is

$$P := P(B, [z]) := \{Bz | z \in [z]\} \tag{2.23}$$

where we have omitted $\tilde{y}$ which can be compensated for by translating the interval vector $[z]$ suitably. The form (2.23) is less suited if $P$ contains points with large norm but is relatively small in diameter. In this case (2.22) is to be preferred. However for $P$ containing small vectors only, (2.23) is adequate and simplifies computations. We will use the latter form since we are primarily concerned to enclose small error terms in parallel-epipeds by rewriting the solution $y_i$ of (2.39) as a floating-point approximation $\tilde{y}_i$ plus an error $\hat{y}_i$ which will be enclosed in an interval $[\hat{y}_i]$:

$$y_i = \tilde{y}_i + \hat{y}_i \tag{2.24}$$

with an approximation

$$\tilde{y}_{i+1} \approx A_i \tilde{y}_i + d_i \tag{2.25}$$

such that

$$\hat{y}_{i+1} = A_i \hat{y}_i + d_i + (A_i \tilde{y}_i - \tilde{y}_{i+1}) \ . \tag{2.26}$$

For $i = 0$ we choose $\tilde{y}_0 = y_0$ if $y_0$ is a vector of floating-point numbers, otherwise we round $y_0$ to a floating-point vector and enclose the roundoff error $\hat{y}_0$ in an interval vector $[\hat{y}_0] = \diamondsuit(y_0 - \tilde{y}_0)$.

To compute an enclosure of the error $\hat{y}_{i+1}$ we now arrange the computation in such a way that we enclose the result of each iteration in a parallel-epiped, i.e. $\hat{y}_{i+1} \in P(B_{i+1}, [z_{i+1}])$. In each step we introduce a new basis matrix $B_{i+1}$ which we use to represent the resulting parallel-epiped.

Introducing the abbreviation

$$\hat{d}_i = d_i + (A_i \tilde{y}_i - \tilde{y}_{i+1})$$

we replace the iteration (2.26) by

$$\begin{aligned} [z_{i+1}] &:= (B_{i+1}^{-1} A_i B_i)[z_i] + B_{i+1}^{-1}\hat{d}_i, \quad i \geq 0 \\ [\hat{y}_{i+1}] &:= B_{i+1}[z_{i+1}] \end{aligned} \tag{2.27}$$

where $B_{i+1}$ is a regular basis matrix which may be chosen in several different ways to be dicussed later. For $i = 0$ we set $B_0 = I$ and $[z_0] = 0$ or if $\tilde{y}_0 \neq y_0$ then $[z_0] = [\hat{y}_0]$.

The representation of $\hat{y}_i$ as a parallel-epiped $P(B_i, [z_i])$ is used in the first line of (2.27) to compute the interval vector $[z_{i+1}]$ for the parallel-epiped $P(B_{i+1}, [z_{i+1}])$ of the next iteration and in the second line it is used to compute an optimal enclosure $[\hat{y}_{i+1}]$ of this parallel-epiped. This enclosure however is used only for projecting the result to orthogonal coordinates (which is convenient for output purposes) and *not* for further computations which would bring back again the wrapping effect.

We see that in this modified algorithm in each step we need an inverse of the new basis matrix $B_{i+1}$. Although we will always choose basis matrices which are exactly representable on the computer we still cannot get exact inverses in floating-point so that we have to compute an enclosure of $B_{i+1}^{-1}$ instead, i.e. we use Algorithm 2.2.4 of Section 2.1 for this purpose. We also note that the product $A_i B_i$ cannot be computed exactly on the computer so that we will in general obtain an interval matrix instead even if $A_i$ is also a floating-point matrix. In many cases even $A_i$ will already be an interval matrix.

Next, we turn to the choice of the basis matrices $B_i$. There are many possibilities for this choice some of which we will discuss now. A trivial possibility is

$$B_i := I, \quad i \geq 0 \ . \tag{2.28}$$

In this simple special case our new algorithm (2.27) reduces to the previous ordinary one, (2.39), where we computed just an interval vector as enclosing set in each iteration.

A more sophisticated choice is

$$B_0 := I, \quad B_{i+1} := \mathrm{mid}(\diamondsuit A_i B_i) \ , i \geq 0, \tag{2.29}$$

where we have taken into account that $A_i B_i$ is an interval matrix in general on the computer, as discussed above. This choice means that $B_{i+1}$ approximates the product $A_i \cdots A_0$. However, as we can see in the very common case when the $A_i$ are independent of $i$ then this product is the power $A^{i+1}$ which becomes very ill-conditioned if $A$ has eigenvalues with different real parts, since then the eigenvector for the largest eigenvalue dominates the columns of $A^{i+1}$ which are therefore close to being linearly dependent.

Thus we must expect the matrices $B_{i+1}$ to become ill-conditioned or even singular very soon. Since we need the inverse of this matrix in (2.27) we must expect the iteration to yield rapidly growing enclosures or even to break down after few iterations. Only in the case where the $A_i$ are orthogonal or nearly orthogonal the matrices $B_{i+1}$ will stay well behaved for many iteration. E.g. in Example 2.1 this choice of $B_{i+1}$ would be adequate and almost eliminate the wrapping effect, since there $A$ is an orthogonal matrix independent of $i$.

The problems which are caused by this choice of $B_{i+1}$ are eliminated if we force $B_{i+1}$ to be a regular and even well-conditioned matrix by choosing it always as an orthogonal matrix. I.e. instead of the choice (2.29) we first carry out a $QR$-decomposition of the matrix $\mathrm{mid}(\diamondsuit A_i B_i)$ and take only the orthogonal part $Q$ as new basis matrix:

$$B_{i+1} := Q_{i+1}, \quad \text{where} \quad \tilde{B}_{i+1} = \mathrm{mid}(\diamondsuit A_i B_i), \quad \tilde{B}_{i+1} \approx Q_{i+1} R_{i+1} \ . \tag{2.30}$$

Here $Q_{i+1}R_{i+1}$ is an approximate $QR$-decomposition of $\tilde{B}_{i+1}$. $Q$ is almost orthogonal and $R$ is an upper triangular matrix. It is completely sufficient to carry out this approxiate decomposition in floating-point arithmetic without verification. We do not present the details here since we will use a standard numerical algorithm which gives $Q$ as the product of Housholder matrices (see e.g. [309] or [308]). This algorithm is listed in the next subsection. Now we know that $B_{i+1}$ is almost orthogonal and thus a regular and well-conditioned matrix. Geometrically this choice of the basis matrices means that we take only rotated hyper-rectangles as enclosing sets thus avoiding long and thin parallel-epipeds whose corners depend very sensitively on changes in the direction of the edges.

The choice of orthogonal or in our case almost orthogonal basis matrices $B_i$ has another advantage here. As we saw in (2.27) we need an enclosure of the inverse of $B_i$. For an orthogonal matrix $Q$ we have $Q^{-1} = Q^T$ and thus for an almost orthogonal matrix $Q$ the transposed matrix is a good approximation of the inverse $Q^T \approx Q^{-1}$. In this case we have even a very good rigorous estimate of the error by use of the Neumann series i.e. we do not need the algorithms from Section 2.1 for enclosing the inverse, but rather we can compute an enclosure of $Q^{-1}$ directly.

For an almost orthogonal matrix we have

$$||I - QQ^T||_\infty = q << 1$$

where we take the $||\cdot||_\infty$ norm for convenience.

If we compute $Q$ in floating-point arithmetic by Housholder transformations, say, then we can observe that $q$ is only little larger than the order *eps* of the relative machine accuracy.

An enclosure $[Q^{-1}]$ of the inverse of $Q$ now follows immediately from the Neumann series

$$Q^{-1} \in [Q^{-1}] := Q^T + [-\epsilon, \epsilon] \begin{pmatrix} 1 & \cdots & 1 \\ \vdots & & \vdots \\ 1 & \cdots & 1 \end{pmatrix} \tag{2.31}$$

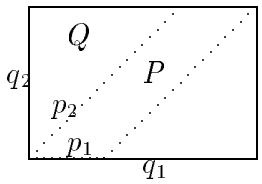
where

$$\epsilon = \frac{q}{1-q} \ ||Q^T||_\infty \ . \tag{2.32}$$

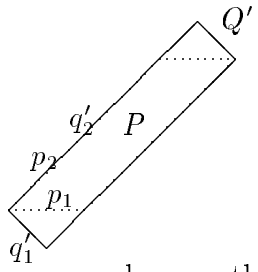
There is an additional trick, however, which we should also apply since otherwise the resulting intervals would very oddly depend on the order of the rows in $A_i$ i.e. on the order of the components in equation (2.39) since reordering the rows of $A_i$ changes the matrix $Q_i$ which is computed in (2.30).

We avoid this by reordering the columns of $\tilde{B}_{i+1}$ prior to the $QR$-decomposition in the following way. From (2.27) we see that the shape of the parallel-epiped $P(\tilde{B}_{i+1}, [z_i])$ is an approximation of the shape of the solution set in the $(i+1)$-st step (we have ommited the translational part $d_i$ which does not alter this shape). Therefore the edges of the solution set are approximately parallel to the columns of $\tilde{B}_{i+1}$. Then the length of each edge is the length of the corresponding column multiplied by the diameter of the same component in the interval vector $[z_i]$. Now orthogonalizing $\tilde{B}_{i+1}$ means that we start with the edge in direction of the first column, leave it fixed and make the edge in direction of the second column orthogonal to the first one. The same will be done with the other edges. From this geometric interpretation we can deduce that we will obtain a smaller enclosure if we perform the orthonormalization process starting with the longest edge and then orthogonalizing the edges with successively decreasing lengths.

The following picture illustrates this situation for a parallel-epiped in the plane. There the edges of the parallel-epiped $P$ (dotted lines) which is spanned by $p_1, p_2$ are orthogonalized in two different orders leaving first the shorter direction $p_1$ first to obtain a rectangle $Q$ spanned by $q_1, q_2$ and then, second, leaving the longer direction $p_2$ fixed obtaining a rectangle $Q'$ spanned by $q_1', q_2'$. Both rectangles enclose the parallel-epiped $P$ but $Q'$ is a much better enclosure than $Q$ since the direction of the longest edge $q_2'$ of $Q'$ coincides with that of the longest edge $p_2$ of $P$.



Keep $p_1$, make $p_2$ orthogonal to $p_1$



Keep $p_2$, make $p_1$ orthogonal to $p_2$

This results in the following modified rule for the choice of $B_{i+1}$

$$B_{i+1} := Q_{i+1}, \quad \text{where} \quad \tilde{B}_{i+1} = \text{mid}(\diamondsuit A_i B_i), \quad \tilde{B}_{i+1} P_{i+1} \approx Q_{i+1} R_{i+1} \ . \tag{2.33}$$

and $P_{i+1}$ is the permutation matrix which reorders the columns of $\tilde{B}_{i+1}$ in the way described above.

Putting together the pieces, we now have a method for enclosing the solution $y_i, i \geq 0$ of a vector difference equation of the form (2.21):

Algorithm for first order vector difference equations:

1. compute an approximation $\tilde{y}_{i+1}$ (as a vector of floating-point numbers), (2.25).
2. compute an enclosure $[\hat{y}_{i+1}]$ of the error $\hat{y}_{i+1}$ by use of (2.27), choose $B_{i+1}$ according to (2.33) and compute an enclosure of $B_{i+1}^{-1}$ as in (2.31).

Obviously, this algorithm can even be applied if already the starting vector is an interval vector $y_0 = [y_0]$. Then we set $\tilde{y}_0 \approx \mathrm{mid}([y_0])$ and $[z_0] = [y_0] - \tilde{y}_0$ ( and of course $B_0 = I$).

Now we turn to the case of scalar difference equations. We call the following recursive equations

$$\begin{aligned} &x_0, \ldots, x_{m-1} \quad \text{given} \\ &a_{i,m}x_{i+m} + \cdots + a_{i,0}x_i = b_i, \quad i \geq 0, \end{aligned} \tag{2.34}$$

a (scalar) linear difference equation of order $m$. The $m$ starting values $x_0, \ldots, x_{m-1}$ are given and if we assume all $a_{i,m} \neq 0$ then the solution $x_m, x_{m+1}, \ldots$ can be computed recursively by

$$x_{i+m} = \frac{b_i}{a_{i,m}} - \frac{a_{i,0}}{a_{i,m}}x_i - \cdots - \frac{a_{i,m-1}}{a_{i,m}}x_{i+m-1} \ . \tag{2.35}$$

As we saw in Example 2.3 in the previous section, if we use interval arithmetic a recursively computed solution can yield rapidly growing intervals due to the wrapping effect. From Example 2.1 which is a first order difference equation for a matrix-vector equation, we know a geometric interpretation of this effect which will enable us to modify the computation in order to reduce the wrapping.

To this end we rewrite (2.34) as a first order matrix-vector equation by introducing the vectors

$$y_i := (x_i, \ldots, x_{i+m-1})^T \in \mathbb{R}^m, \quad i \geq 0, \tag{2.36}$$

$$d_i := (0, \ldots, 0, b_i/a_{i,m})^T \in \mathbb{R}^m, \quad i \geq 0, \tag{2.37}$$

and the matrices

$$A_i := \begin{pmatrix} 0 & 1 & \cdots & 0 & 0 \\ 0 & 0 & \ddots & 0 & \vdots \\ \vdots & \vdots & \ddots & \vdots & 0 \\ 0 & 0 & & 1 & 0 \\ 0 & 0 & \cdots & 0 & 1 \\ \dfrac{-a_{i,0}}{a_{i,m}} & \dfrac{-a_{i,1}}{a_{i,m}} & \cdots & \dfrac{-a_{i,m-2}}{a_{i,m}} & \dfrac{-a_{i,m-1}}{a_{i,m}} \end{pmatrix} \in \mathbb{R}^{m\times m} \ . \tag{2.38}$$

Then the scalar $m$-th order equation (2.34) can be rewritten as the first order vector difference equation

$$y_{i+1} = A_i y_i + d_i, \quad i \geq 0 \tag{2.39}$$

with

$$y_0 = (x_0, \ldots, x_{m-1})^T \ , \tag{2.40}$$

which is exactly of the form (2.21).

Computing (2.39) directly in interval arithmetic is equivalent to the naive forward computation of (2.34) in interval arithmetic from which the reason of the severe overestimations becomes clear now also for scalar difference equations: they are just a special case of general first order vector difference equations and thus also subject to the wrapping effect.

Therefore we compute the solution $x_m, x_{m+1}, \ldots$ of (2.34) by using the equivalent vector form (2.39) and applying the algorithm discussed above for such equations.

#### 2.2.2.2 Algorithms

We start this section by first listing some small auxiliary algorithms which will be needed later in the enclosure algorithm for the solution of difference equations.

The following algorithm sorts the columns of the input matrix $B$ according to the lengths of the edges of the parallel-epiped $P(B, z)$ where the interval vector $z$ is the second input parameter. The procedure SWAP used here swaps the contents of its two parameters.

### Algorithm 2.7: SortColumns $(B, z)$ {procedure}

{Sort the columns of B by decreasing length of the edges of P(B,z)}
**input:** *rmatrix* $B$, interval vector $z$
**output:** *rmatrix* $B$ with columns rearranged

(a) {compute lengths of edges (squares of these lengths suffice):}
**for** $i := 1$ **to** $m$ **do** $length_i := (B_{*,i} \cdot B_{*,i}) \cdot \mathrm{diam}(z_i)^2$

(b) {sort columns of B according to these lengths}
**for** $i := 1$ **to** $m - 1$ **do**
**for** $j := i + 1$ **to** $m$ **do**
**if** $length_i < length_j$ **then** Swap $(B_{*,i}, B_{*,j})$
Swap $(length_i, length_j)$

(c) **return** $B$

Next an algorithm is presented which computes an approximate $QR$-decomposition of the input matrix $A$ in ordinary floating-point arithmetic. We did not present the theory for this method in the previous section since this is a standard algorithm, see e.g. [309]. The matrix $A$ is successively multiplied with Householder matrices to bring it in triangular form $R$. The orthogonal part $Q$ is then the accumulated product of the Housholder matrices.

### Algorithm 2.8: QR $(A)$ {function}

{floating-point computation of the QR-decomposition of $A$ }
**input:** *rmatrix* $A$
**output:** almost orthogonal matrix $Q$ (function result)

(a) {start with identity matrix}
$Q := I$

(b) {loop over all columns of $A$ (but the last)}
**for** $k := 1$ **to** $m-1$ **do**
$b := A_{k..n,k}$ { $b$ is $(n-k+1)$-vector }
**if** $b \neq 0$ **then**
$s := -\text{sign}(A_{k,k}) \cdot \|b\|_2$
$b_k := A_{k,k} - s$
$s := 1/(s \cdot b_k)$
{eliminate entries below diagonal in $A$:}
**for** $i := k+1$ **to** $n$ **do**
$r := s \cdot (b \cdot A_{k..n,i})$
**for** $j := k$ **to** $n$ **do** $A_{j,i} := A_{j,i} + b_j \cdot r$
{accumulate product of Householder matrices in $Q$:}
**for** $i := 1$ **to** $n$ **do**
$r := s \cdot (Q_{i,k..n} \cdot b)$
**for** $j := k$ **to** $n$ **do** $Q_{i,j} := Q_{i,j} + b_j \cdot r$

(c) {return function value}
QR $:= Q$

The next algorithm is a function which computes an enclosure of the inverse of an almost orthogonal matrix $Q$ using the estimates of the Neumann series. An error code 1 is returned if the norm $q = ||I - Q^T Q||_\infty \geq 1$, otherwise an error code 0 is returned.

## Algorithm 2.9: Inv $(Q, err\_code)$ {function}

{Enclosure of the inverse of an almost orthogonal matrix $Q$ }
**input:** *rmatrix* $Q$ (almost orthogonal)
**output:** Enclosure of $Q^{-1}$ as *imatrix* (function result), *integer* *err_code* indicating successful inversion (=0 or =1 otherwise).

(a) {norm of residuum}
$q := \|I - Q^T Q\|_\infty$
**if** $q \geq 1$ **then** $err\_code := 1$ **else** $err\_code := 0$
**if** $err\_code = 1$ **then return**

(b) $\epsilon := \|Q^T\|_\infty \cdot q/(1-q)$
**for** $i := 1$ **to** $m$ **do**
**for** $j := 1$ **to** $m$ **do**
$Q1_{i,j} := Q_{j,i} + [-\epsilon, \epsilon]\|Q^T\|_\infty$

(c) {return enclosure of inverse as function value:}
Inv $:= Q1$

The following algorithm computes an enclosure of the solution of a first order vector difference equation using the coordinate transformation with orthogonal basis matrices as discussed in the previous section. In the algorithm only one step is computed, the input for the algorithm is a parallel-epidped $P_0$(y0,B0,z0) and output is a parallel-epiped $P_1$(y1,B1,z1). To obtain a component-wise interval enclosure of $P_1$ the interval vector y1 + B1*z1 must be computed after a call to this algorithm.

The input matrix A ($=A_i$) and the input vector d ($=d_i$) are chosen as interval vectors here to allow for interval data and for non floating-point data (enclosed in intervals).

## Algorithm 2.10: MatVecIter $(A, d, y0, B0, z0, y1, B1, z1)$ {procedure}

{Compute one step of the matrix-vector iteration $y_{i+1} = Ay_i + d_i$ }
**input:** *imatrix* $A = (A_i)$, *rmatrix* $B0 = (B_i)$ (from previous step), *ivector* $d = (d_i)$, *rvector* $y0 = (\tilde{y}_i)$ and *ivector* $z0 = ([z_i])$ (from previous step).
**output:** *rvector* $y1 = (\tilde{y}_{i+1})$, *rmatrix* $B1 = (B_{i+1})$ and *ivector* $z1 = ([z_{i+1}])$.

(a) {compute approximation}
$y1 := \mathrm{mid}(A) \cdot y0 + \mathrm{mid}(d)$

(b) {enclosure of the error}
$B1 := \mathrm{mid}(A) \cdot B0$
SortColumns $(B1, z0)$
QR $(B1)$
$BI1 :=$ Inv $(B1, err\_code)$
**if** $err\_code = 1$ **then** print warning: inversion not successful
$z1 := (BI1 \cdot A \cdot B0) \cdot z0 + BI1 \cdot \diamondsuit(d + A \cdot y0 - y1)$

(c) **return** $y1, B1, z1$

Finally we list an algorithm for the computation of the solution of a scalar difference equation of order $m$. It is essentially identical with the previous algorithm 2.2.10 for first order vector difference equations, only the form of the input is different, i.e. here we only need an ivector a, containing the coefficients $a_0, \ldots, a_m$ and an interval b for $b_i$.

In this algorithm we use a pseudo-function `COEFF` which should just be an indication than its argument should not be interpreted as a vector but rather as a matrix of the form (2.38) containing the coefficients of the argument vector in the way indicated in (2.38).

## Algorithm 2.11: DiffIter $(A, b, y0, B0, z0, y1, B1, z1)$ {procedure}

{Compute one step of the scalar iteration with the difference equation $a_{i,m}x_{i+m} + \cdots + a_{i,0}x_i = b_i$ }
**input:** *ivector* $A$ (coefficient vector), *interval* $b$ (right hand side), *rmatrix* $B0 = (B_i)$ (from previous step), *rvector* $y0 = (\tilde{y}_i)$ and *ivector* $z0 = ([z_i])$ (from previous step).
**output:** *rvector* $y1 = (\tilde{y}_{i+1})$, *rmatrix* $B1 = (B_{i+1})$ and *ivector* $z1 = ([z_{i+1}])$.

(a) {compute floating-point approximation}
$y1_{1..m-1} := y0_{2..m}$
$y1_m := (\mathrm{mid}(b) - \sum_{i=1}^{m} \mathrm{mid}(a_{i-1}) \cdot y0_i)/\mathrm{mid}(a_m)$

(b) {enclosure of the error}
$B1 :=$ Coeff $(\mathrm{mid}(A)) \cdot B0$
SortColumns $(B1, z0)$
QR $(B1)$

$BI1 := \mathsf{Inv}(B1)$
$d := \diamondsuit(b - \sum_{i=1}^{m} a_{i-1} \cdot y0_i)/a_m - y1_m$
$z1 := (BI1 \cdot (\mathsf{Coeff}(A) \cdot B0)) \cdot z0 + BI1_{*,m} \cdot d$

(c) **return** $y1, B1, z1$

#### 2.2.2.3 PASCAL-XSC Program Code

The following PASCAL-XSC module contains the algorithms from the previous section and exports the last two algorithms `Mat_Vec_Iter` and `Diff_Iter` as global entries.

```
MODULE mv_differ;

```

#### 2.2.2.4 Test Results

To test the first order matrix-vector difference equations we use the following simple iteration which is a two-dimensional rotation around the origin by an angle $\phi$ with $\cos\phi = 0.6$ and $\sin\phi = 0.8$.

$$y_{i+1} = \begin{pmatrix} 0.6 & 0.8 \\ -0.8 & 0.6 \end{pmatrix} y_i \quad , \quad i \geq 0, \qquad y_0 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} . \tag{2.41}$$

The following short program is written for the simple case of $A_i$ and $d_i$ being independent of $i$. It reads the dimension $n$ the matrix $A$, the vector $d$ the initial vector $y_0$ and the number of iterations to be performed. It prints out the results obtained by applying parallel-epipeds with orthogonal basis matrix as described in (2.33) and the results computed without any basis transformation i.e. by forward computation in plain interval arithmetic ( $B_i = I$ for alls $i$).

```
program mv_iteration;

USE i_ari,mv_ari,mvi_ari,mv_differ;

PROCEDURE main( m : INTEGER );
VAR i,n,err_code  : INTEGER;
    A             : imatrix[1..m,1..m];
    B0,B1         : rmatrix[1..m,1..m];
    y0,y1         : rvector[1..m];
    z0,z1,x0,x1,d : ivector[1..m];
BEGIN
   WRITE('A  = '); READ(A);
   WRITE('d  = '); READ(d);
   REPEAT
      WRITE('x0 = '); READ(x0);
      WRITE('n  = '); READ(n);

      B0:= id(B0);
      y0:= mid(x0);
      z0:= x0 - y0;

      FOR i:= 1 TO n DO
      BEGIN
         mat_vec_iter( A,d, B0,z0,y0, B1,z1,y1, err_code );
         x1:= A*x0 + d;
         IF err_code <> 0 THEN WRITELN('Error in iteration ',i );
         WRITELN('i = ',i:3);
         WRITE('orthogonal basis Q :'); WRITE( y1 + B1*z1 );
         WRITE('no transformation  :'); WRITELN( x1 );
         B0:= B1;
         z0:= z1;
         y0:= y1;
         x0:= x1;
      END;
   UNTIL n <= 0;
END;

VAR m : INTEGER;

BEGIN
   REPEAT
      WRITE('m = '); READ(m);
      IF m > 0 THEN main(m);
   UNTIL m <= 0;
END.
```

The result for our small test system is listed next, where, however most of the output is deleted and only the result for a few selected values of $i$ between 1 and 1000 are printed. Obviously the iteration with the orthogonal basis transformation can still be computed over a far wider range of values of $i$ whereas the straigthforward interval computation is hopelessly bad.

```

### 2.2.3 Band Matrices

Matrices with band structure and difference equations are closely related. We have seen this already in the examples of Section 2.2.1. There the difference equations could be rewritten equivalently as a linear system with band matrix which was triangular even. Similarly we can go in the other direction and write a triangular banded matrix as a difference equation.

The system

$$Ax = \begin{pmatrix} a_{1,1} & & & & \\ \vdots & \ddots & & 0 & \\ a_{m,1} & & \ddots & & \\ & \ddots & & \ddots & \\ 0 & & a_{n,n-m+1} & \cdots & a_{n,n} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ \\ x_n \end{pmatrix} = \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ \\ b_n \end{pmatrix} = b \tag{2.42}$$

is obviously equivalent with the difference equation

$$a_{i,i-m+1}x_{i-m+1} + \cdots + a_{i,i}x_i = b_i \ , \quad i = m, \ldots, n, \tag{2.43}$$

of order $m-1$ with the starting values

$$x_i = (b_i - a_{i,i-1}x_{i-1} - \cdots - a_{i,1}x_1)/a_{i,i} \ , \quad i = 1, \ldots, m-1 \ . \tag{2.44}$$

In the examples in Section 2.2.1 we saw that the solution of triangular systems by interval forward substitution can result in severe overestimations. Therefore we use the relationship to difference equations and solve triangular banded systems with the method for difference equations which was presented in the previous Section.

For general banded systems we will then apply a $LU$-decomposition without pivoting to the coefficient matrix $A$ and derive an interval iteration similar to (2.5). Here, however, we will not use a full approximate inverse $R$ but rather the iteration will be performed by solving two systems with banded triangular matrices ( $L$ and $U$ ).

A similar approach to banded and sparse linear systems can be found in [78], [79] and [295]. There, however, the triangular systems were solved by interval forward and backward substitution which often results in gross overestimations as we have seen already.

For a different approach to the verified solution of linear systems with large banded or arbitrary sparse coefficient matrix see Rump, [292].

#### 2.2.3.1 Theoretical Background

The mathematical background for the verified solution of large linear systems with band matrices is exactly the same as it was already in Section 2.1.2 for systems with dense matrices. To avoid repetition of this section we assume the same notation here.

For dense systems the interval iteration (2.5) was derived by use of an approximate inverse $R$ of the coefficient matrix $A$. This is however what we want to avoid for large banded matrices $A$. Therefore we chose a different approximate inverse, namely

$$R := (LU)^{-1} \approx A^{-1} \tag{2.45}$$

where

$$LU \approx A \tag{2.46}$$

is an approximate $LU$-decomposition of $A$ without pivoting. Since we do not use pivoting both $L$ and $U$ are banded matrices again, and of course they are lower and upper triangular, resp.

The analogue of the iteration (2.5) now reads in our case

$$y_{k+1} = (LU)^{-1}(b - A\tilde{x}) + (I - (LU)^{-1}A)y_k \tag{2.47}$$

or, multiplying with $LU$ and taking intervals:

$$LU[y]_{k+1} = \diamondsuit(b - A\tilde{x}) + \diamondsuit(LU - A)[y]_k. \tag{2.48}$$

Therefore we have to solve two linear systems with triangular, banded coefficient matrices, $L$ and $U$, in order to compute $[y]_{k+1}$, i.e. to perform one step of the iteration (2.48).

In each iteration we first compute an enclosure for the solution of

$$L[z]_{k+1} = \diamondsuit(b - A\tilde{x}) + \diamondsuit(LU - A)[y]_k$$

and then $[y]_{k+1}$ from

$$U[y]_{k+1} = [z]_{k+1}.$$

In both systems we do not use just plain interval forward or backward substitution, however, as discussed above, we treat the systems as difference equation and apply the corresponding method from the previous Section.

Here again, as in Section 2.1.2 the inclusion test

$$[y]_{k+1} = F([y]_k) \subset [y]_k^\circ \tag{2.49}$$

has to be checked in the same way and if it is satisfied then the same assertions hold as in the dense case.

**Remark:**

If we compute the $LU$-decomposition with Crout's algorithm, then we can get the matrix $\diamondsuit(LU - A)$ virtually for free, since the scalar products which are needed here have to be computed in Crout's algorithm anyway.

#### 2.2.3.2 PASCAL-XSC Program Code

The following program implements the method from the last Subsection for the verified solution of linear systems with band matrices. In addition to the implementation of the solution method the program includes also a small demonstration part which can be used to solve some simple systems.

First the program reads the number of lower and upper bands and then one value for each of the bands, i.e. initially a Toeplitz matrix is generated.

In the next step, however, any number of elements of the matrix can be changed, such that also arbitrary band matrices can be entered. To change the element $a_{i,j}$ only $i, j$ and the new value for this element must be entered. Changing elements is finished by entering zeros for $i$ and $j$.

Next the right hand side must be entered. There are several choices of predefined solutions, such that the right hand side $b$ will be determined from this given solution. Alternatively $b$ can be set to a constant value in all components or all components can be entered successively. In any case, the values of the components of $b$ may be changes again similarly as for the matrix. When no changes are done anymore, the solution algorithm starts.

At the end the solution and a brief error statistics is printed out (see next Subsection).

### 2.2.3.3 Test Results

We now present some results which were computed with the program from the previous Subsection.

First we turn back to Example 3 from Section 2.2.1. From interval forward substitution we had there for $x_0 = 0.99$ the enclosure $T_{50}(0.99) \in [-710, 720]$. If we solve the same system (of dimension $n = 51$) with our program we get the following output:

```
 Dimension  n = 51
 Bandwidths l,k :
2 0
 A =
1 -1.98 1
change elements ? (y/n) y
row, col, new value : 2 1 0
row, col, new value : 0 0
 b =
=0
change elements ? (y/n) y
row, new value : 1 1
row, new value : 2 0.99
row, new value : 0 0
x =

max. rel. error =  5.694110624237756E-014  at i = 12
max. abs. error =  8.326672684688674E-016  at i = 32
min. abs. x[12] = [    1.3861676276707E-002,    1.3861676276709E-002 ]
max. abs. x[1] = [  1.000000000000000E+000,  1.000000000000000E+000 ]
```

Thus we get $T_{50}(0.99) \in 0.701149198176929_1^8$ to almost full machine accuracy. Also for higer dimensions we still get excellent enclosures, e.g. $T_{200}(0.99) \in -0.999436889793187_4^1$, $T_{1000}(0.99) \in -0.985953929150054_5^0$ or $T_{5000}(0.99) \in -0.668192579523340_9^1$.

As a second example we compute an enclosure for a very large system. We take the symmetric Toeplitz matrix with five bands having the values $1, 2, 4, 2, 1$ and on the right hand side we set all components of $b$ equal to 1. Then the program produces the following output for a system of size $n = 200000$ (only the first ten and last ten solution components are printed):

```
 Dimension  n = 200000
 Bandwidths l,k :
2 2
 A =
1 2 4 2 1
n
=1
n
change elements ? (y/n)  b =
change elements ? (y/n) x =

# Chapter 3

# Eigenvalue Problems

In this chapter we will demonstrate methods for the inclusion of eigenvalues and eigenvectors of square matrices. We will use two different approaches:

1. A general one which can be applied to any eigenvalue problem which is treated as a nonlinear system of equations by this approach. Here we need, however, a starting approximation for both, an eigenvalue and the corresponding eigenvector. The method then encloses an eigenpair which lies close to the given starting approximation.

2. A method more specialized to symmetric eigenvalue problems which encloses all eigenvalues and eigenvectors of a symmetric matrix. Here we do not need starting approximations. The method will enclose all eigenvalues and eigenvectors of the given symmetric matrix.

Both methods can be equally applied to real, interval, complex and complex interval matrices.

The first method is due to Rump, [280], [285]. We will apply it to the ordinary eigenvalue problem

$$Ax = \lambda x \tag{3.1}$$

as well as to the general eigenvalue problemi

$$Ax = \lambda Bx \quad . \tag{3.2}$$

This method can be viewed as a Newton like interval iteration method for the nonlinear system

$$\begin{pmatrix} Ax - \lambda x \\ e_k^T x - 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

in the case of (3.1) and for the system

$$\begin{pmatrix} Ax - \lambda Bx \\ e_k^T x - 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

in the case of (3.2). (Here $e_k^T$ is the $k$-th unit vector and the last equation in these systems means that the $k$-th component of the eigenvector $x$ is normalized to be 1). Therefore, as mentioned already, we need starting approximations for both the eigenvalues and the eigenvectors. Then only one eigenpair will be enclosed. If we

want to enclose all eigenvalues and eigenvectors of the matrix we also must supply approximations for all of them. A drawback of the method is, that it works only for simple eigenvalues. I.e. multiple eigenvalues and their eigenvectors cannot be enclosed by this method. However, to the authors knowledge for the ordinary eigenvalue problem there does not yet exist a general method which can enclose multiple eigenvalues and their eigenvectors without prior knowledge of their multiplicity.

The second method can be applied to symmetric matrices only, it can also be generalized to complex Hermitian matrices. It consists of two basic steps: First an approximate eigensystem is determined (by use of the Jacobi method in our case). Second, a similarity transformation of $A$ is performed with this approximation and the resulting, usually strongly diagonally dominant matrix is taken to enclose the eigenvalues by use of the Gerschgorin circle theorem. In this second step all roundoff errors are taken into account. Finally, for the enclosure of the eigenvectors we can use standard estimations from Wilkinson, [333], or others. In the first step we can refine the approximate eigensystem by some sort of residual iteration which was introduced in Lohner, [231].

The differences of this second method from the previous one are that it encloses all eigenvalues and eigenvectors of the symmetric matrix simultaneously and independently of the multiplicities of the eigenvalues (which are all real here) and that this method does not need any approximations of the eigenvalues and eigenvectors.

The first method will be applied to the ordinary eigenvalue problem in the next Section 3.1 and to the general eigenvalue problem in Section 3.2. Then, in Section 3.3 we will apply the second method to the symmetric eigenvalue problem.

Other approaches to the verified solution of eigenvalue problems can be found in the work of Goerisch and Behnke, [34], [35], [36], [112]. The methods developed there are based on variational principles and more general theorems and are therefore also suited for the application to eigenvalue problems with differential and integral equations.

## 3.1 The Eigenvalue Problem $Ax = \lambda x$

### 3.1.1 Introduction

Here we discuss a method for the computation of enclosures of a simple eigenvalue $\lambda$ and its associated eigenvector $x$ of the ordinary matrix eigenvalue problem (3.1). This enclosure method was introduced by Rump, [280], [285], and can be interpreted as a Newton like iteration method for a zero of the function $f : \mathbb{R}^{(n+1)} \to \mathbb{R}^{(n+1)}$ with

$$f(x, \lambda) := \begin{pmatrix} Ax - \lambda x \\ e_k^T x - 1 \end{pmatrix} \tag{3.3}$$

and an $n \times n$-matrix $A$. See also [244] for a discussion of this method.

The last component of $f$ forces the eigenvector $x$ to have the $k$-th component equal to one ($e_k$ is the $k$-th unit-vector). Any other normalization of $x$ could also be

used (e.g. $x^T x - 1 = 0$), however the one we have chosen makes some things easier to be written down and simplifies the computation somewhat.

We stress again that for this method we need an approximate eigenvalue $\tilde{\lambda}$ and an approximate eigenvector $\tilde{x}$ and that this method can only be used to enclose eigenpairs corresponding to a simple eigenvalue $\lambda$.

The approximations which are needed can be computed by any method, a popular one which can also be found in many software libraries is the QR-method, see e.g. [309] or [308].

The method can be easily extended to different data types like interval, complex and complex interval.

### 3.1.2 Theoretical Background

Assume we have an approximation $\tilde{\lambda}$ of an eigenvalue $\lambda$ and $\tilde{x}$ of the corresponding eigenvector $x$ of the eigenvalue problem (3.1). Then we denote the error of these approximations by

$$\begin{pmatrix} y \\ \mu \end{pmatrix} = \begin{pmatrix} x - \tilde{x} \\ \lambda - \tilde{\lambda} \end{pmatrix} . \tag{3.4}$$

Substituting $x = \tilde{x} + y$ and $\lambda = \tilde{\lambda} + \mu$ in (3.3) we get

$$\begin{aligned} f(x,\lambda) &= f(\tilde{x} + y, \tilde{\lambda} + \mu) \\ &= \begin{pmatrix} A(\tilde{x} + y) - (\tilde{\lambda} + \mu)(\tilde{x} + y) \\ e_k^T(\tilde{x} + y) - 1 \end{pmatrix} \\ &= \begin{pmatrix} A\tilde{x} - \tilde{\lambda}\tilde{x} \\ e_k^T\tilde{x} - 1 \end{pmatrix} + \begin{pmatrix} Ay - \tilde{\lambda}y - \mu(\tilde{x} + y) \\ e_k^T y \end{pmatrix} \\ &= f(\tilde{x}, \tilde{\lambda}) + \begin{pmatrix} A - \tilde{\lambda}I & -(\tilde{x} + y) \\ e_k^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} \end{aligned}$$

where $I$ is the $n \times n$ identity matrix.

Multiplying $f(x, \lambda) = 0$ with this representation of $f$ by an $(n+1) \times (n+1)$-matrix $-C$ and adding $(y, \mu)^T$ to both sides we obtain an equivalent equation which is in fixed point form.

With the function

$$g(y,\mu) = -Cf(\tilde{x}, \tilde{\lambda}) + (I_{n+1} - C \begin{pmatrix} A - \tilde{\lambda}I & -(\tilde{x} + y) \\ e_k^T & 0 \end{pmatrix}) \begin{pmatrix} y \\ \mu \end{pmatrix} \tag{3.5}$$

where $I_{n+1}$ is the $(n+1) \times (n+1)$ identity matrix, this fixed point form is

$$\begin{pmatrix} y \\ \mu \end{pmatrix} = g(y,\mu) . \tag{3.6}$$

If $C$ is non-singular then the fixed points $(y^*, \mu^*)$ of $g$ are just the values for which $x = \tilde{x} + y^*$ and $\lambda = \tilde{\lambda} + \mu^*$ are the eigenpairs of $A$. We will compute enclosures for these fixed points by use of an interval iteration based on (3.6):

$$\begin{pmatrix} [y_{k+1}] \\ [\mu_{k+1}] \end{pmatrix} = g([y_k], [\mu_k]), \quad k \geq 0 \ , \tag{3.7}$$

with a suitable starting interval $([y_0], [\mu_0])^T$, see below. Then in (3.5) we must of course use interval operations to evaluate $g$.

If for this interval iteration we have an index $k$ for which an interval vector $([y_k], [\mu_k])^T$ is mapped into its interior

$$\begin{pmatrix} [y_{k+1}] \\ [\mu_{k+1}] \end{pmatrix} = g([y_k], [\mu_k]) \subseteq \quad \text{int} \begin{pmatrix} [y_k] \\ [\mu_k] \end{pmatrix} \tag{3.8}$$

then we can apply Brouwer's fixed point theorem to prove the existence of a fixed point of $g$.

If condition (3.8) holds then we can even show the following assertions, which are proved e.g. in [280], [285] or in [244] :

1. The matrix $C$ is non-singular.
2. In $(\tilde{x} + [y_k], \tilde{\lambda} + [\mu_k])$ there is a unique eigenpair of $A$.
3. The corresponding eigenvalue is simple.
4. If iteration (3.7) is continued with the interval $([y_k], [\mu_k])^T$ from (3.8) then the iterates are contained successively in each other and they converge monotonely decreasing to the enclosed unique eigenpair.

For the practical application of this iteration on the computer we must, however, specify some steps more detailed: How do we choose the matrix $C$? Which starting vector $([y_0], [\mu_0])^T$ do we use? Can we guarantee that at some index we achieve condition (3.8)?

A good choice for $C$ is usually an approximate inverse of the matrix

$$R := \begin{pmatrix} A - \tilde{\lambda} I & -\tilde{x} \\ e_k^T & 0 \end{pmatrix} \tag{3.9}$$

i.e. $C \approx R^{-1}$ since then the iteration matrix $I_{n+1} - C(R - \begin{pmatrix} 0 & y \\ 0 & 0 \end{pmatrix})$ in (3.5), (3.6) will be close to the zero matrix if $\tilde{\lambda}$ and $\tilde{x}$ are sufficiently good (i.e. $y$ is sufficiently small).

The starting vector for the iteration can be simply chosen to be the zero vector, $([y_0], [\mu_0])^T = (0, 0)^T$. In the next iteration then $([y_1], [\mu_1])^T = -Cf(\tilde{x}, \tilde{\lambda})$, so this vector is a similarly simple starting vector which we will use in our algorithm.

Finally, in order to achieve condition (3.8) at some iteration index $k$ we introduce an $\epsilon$-inflation in the same way as we have used it already in (2.8) in Section 2.1 of Chapter 2. Thus in each iteration step before applying the iteration function $g$ we first inflate the old iterate by a certain amount.

In order to improve the accuracy of the results and to keep the number of interval iterations small we introduce additionally a floating-point iteration to improve the quality of the approximations $\tilde{x}$ and $\tilde{\lambda}$

$$\begin{pmatrix} \tilde{x}_{k+1} \\ \tilde{\lambda}_{k+1} \end{pmatrix} = \begin{pmatrix} \tilde{x}_k \\ \tilde{\lambda}_k \end{pmatrix} - Cf(\tilde{x}_k, \tilde{\lambda}_k) \tag{3.10}$$

until some stopping criterion is satisfied. After this iteration we redefine $\tilde{x}$ and $\tilde{\lambda}$ to be the final values from this floating-point iteration.

Altogether we now obtain the following steps for our enclosure method.

1. Compute an approximate eigenpair $(\tilde{x}, \tilde{\lambda})$ (using any available software).

2. Compute an approximate inverse $C \approx R^{-1}$, with $R$ from (3.9).

3. Improve $\tilde{x}$ and $\tilde{\lambda}$ by performing the floating-point iteration (3.10).

4. Set $([y_0], [\mu_0])^T = (0, 0)^T$.

5. Iterate $([\hat{y}_k], [\hat{\mu}_k])^T = blow([y_k], [\mu_k])^T$, $([y_{k+1}], [\mu_{k+1}])^T = g([\hat{y}_k], [\hat{\mu}_k])$ until an index $k$ is reached for which $([y_{k+1}], [\mu_{k+1}])^T \subseteq \text{int}([\hat{y}_k], [\hat{\mu}_k])^T$, i.e. condition (3.8) is satisfied, or until some specified maximal iteration count is exceeded.

6. If (3.8) was satisfied then $(\tilde{x} + [y_k], \tilde{\lambda} + [\mu_k])^T$ is the desired enclosure of a simple eigenpair of $A$. Otherwise the algorithm did not succeed (e.g. the approximation of the eigenpair was too bad, or the eigenvalue is not simple of the problem is too bad conditioned).

We note that in the interval iteration we do not have to recompute the iteration matrix in each step completely. Since only the last column of this matrix depends on the iterates, see (3.5), we can compute columns $1, \ldots, n$, prior to the iteration. Then in each step we only compute the $(n+1)$-st column $e_{n+1}^T - C\begin{pmatrix} -(\tilde{x}+y) \\ 0 \end{pmatrix}$.

**Remark:**

As is the case of dense systems of linear equations we can use for $C$ an approximate inverse of double length $C = C_1 + C_2$, compare Section 2.1, which can be computed in the same way as in (2.10). With such a double length approximate inverse many more ill-conditioned eigenpairs can be computed as with a single length $C$ only.

### 3.1.3 Algorithms

The algorithm for the computation of enclosures for the eigenvalue and eigenvector of a real matrix $A$ according to the previous Section is listed below. The floating-point approximation $\tilde{x}$ of the eigenvector is assumed to be normalized to one in the $k$-th component already.

**Algorithm 3.1:** Eig $(A, lam, rx, ilam, ix, errcode)$ {procedure}

{Enclosure of an eigenpair for the eigenvalue problem $Ax = \lambda x$}
**input:** real matrix $A$, real $lam$ (appr. eigenvalue), real vector $rx$ (appr. eigenvector)
**output:** interval $ilam$ (eigenvalue enclosure), interval vector $ix$ (eigenvector enclosure), integer $errcode$ (error indicator)

(a) initialize errcode :
$errcode := 0$

(b) compute approximate inverse :
$R := \begin{pmatrix} A - lam \cdot I & -rx \\ e_k^T & 0 \end{pmatrix}$
$C :=$Minv$(R, errcode)$
**if** $errcode \neq 0$ **then** stop

(c) improve floating-point approximation :
$(rx_{old}, lam_{old}) := (rx, lam)$
**repeat**
$(rx, lam) := (rx, lam) - C \cdot (A \cdot rx_{old} - lam_{old} \cdot rx_{old}, e_k \cdot rx_{old} - 1)$
**until** $(rx, lam)$ accurate enough **or** max. iteration count exceeded

(d) compute enclosure of defect of floating-point approximation :
$D := -C \cdot \begin{pmatrix} \diamondsuit(A \cdot rx - lam \cdot rx) \\ 0 \end{pmatrix}$

(e) perform interval iteration :
$Z := D$ { starting vector }
$M :=$ id$(C) - C \cdot \begin{pmatrix} \diamondsuit(A - lam \cdot I) & -rx \\ e_k^T & 0 \end{pmatrix}$ { iteration matrix }
**repeat**
{ compute last column of iteration matrix : }
$M_{*,n+1} := e_{n+1}^T - C \cdot \begin{pmatrix} -rx - Z_{1..n} \\ 0 \end{pmatrix}$
$Z_A :=$ blow$(Z, \epsilon)$ { $\epsilon$-inflation }
$Z := D + M \cdot Z_A$
**until** $Z \subseteq$ int$(Z_A)$ **or** max. iteration count exceeded

(f) return result :
**if** $Z \subseteq$ int$(Z_A)$ **then**
$ilam := lam + Z_{n+1}$ { eigenvalue enclosure }
$ix := rx + Z_{1..n}$ { eigenvector enclosure }
**else**
$errcode := 1$

(g) **return** $ilam, ix, errcode$

### 3.1.4 PASCAL-XSC Program Code

The PASCAL-XSC program code of the method is listed in the following module `eig` for the data type real. The changes which have to be made in order to get modules

`ieig`, `ceig` and `cieig` for the solution of eigenvalue problems with interval, complex and complex interval data types, resp., are almost the same as the changes which were necessary to convert the module `lss` in Section 2.1 to these data types. To do this conversion the changes mentioned there should be applied appropriately to the module `eig`.

The program in this module differs from the previous algorithm slightly in its data structure: instead of using $(n+1)$-vectors and $(n+1) \times (n+1)$-matrices we replace the $k$-th component of $x$ by the eigenvalue $\lambda$ since this component does never change because of the normalization of the eigenvector. Similarly the $k$-th column of the iteration matrix is replaced by the $(n+1)$-st column of the previous notation. The $(n+1)$-st row of this matrix can be omitted completely since it is never used. Thus all matrices and vectors in the program are of dimension $n$ only.

### 3.1.5 Test Results

We demonstrate the use of the module `eig` by the following short PASCAL-XSC program which reads in a matrix $A$ and eigenvalue and eigenvector approximations. Procedure `EIG` from the module `eig` is then used to enclose an eigenpair which is close to the given approximation. The approximations can be entered repeatedly until 'n' or 'N' is entered in procedure `main`. Then a new dimension $n$ and another matrix $A$ may be entered, otherwise the program stops (if $n \leq 0$ is entered).

```
PROGRAM eigtest;

USE i_ari,mv_ari,mvi_ari,eig;

PROCEDURE MAIN( N : INTEGER );

VAR ERR : INTEGER;
    A   : RMATRIX[1..N,1..N];
    EV  : RVECTOR[1..N];
    EW  : REAL;
    IEV : IVECTOR[1..N];
    IEW : INTERVAL;
    OK  : BOOLEAN;
    C   : CHAR;

PROCEDURE WRITE_EW;
VAR J : INTEGER ;
BEGIN
   WRITELN;
   WRITELN('Eigenvalue  = ', IEW );
   WRITELN('Eigenvector = ', IEV );
END { WRITE_EW };

BEGIN
   WRITELN('A = '); READ(A);

   REPEAT
      WRITE('Eigenvalue  approximation : ');  READ(EW);
      WRITE('Eigenvector approximation : ');  READ(EV);

      EIG( A,EW,EV,IEW,IEV,ERR );
      OK:= ERR=0;

      IF OK THEN  WRITE_EW  ELSE
      BEGIN
         WRITELN;
         WRITELN( 'Verification not succeeded. errcode = ', ERR );
      END;

      WRITELN;
      WRITE( 'another eigenvalue ? (y/n) ' );
      READLN; READ(C);

   UNTIL C IN ['N','n'];
END;

VAR N : INTEGER ;

BEGIN
   REPEAT
      WRITE(' N ? (End = 0) '); READ(N);
      IF N>0 THEN MAIN( N );
```

```
   UNTIL N<=0;
END.
```

As an example we use the $3 \times 3$ matrix from [113]

$$\begin{pmatrix} 33 & 16 & 72 \\ -24 & -10 & -57 \\ -8 & -4 & -17 \end{pmatrix}$$

with the eigenvalues $\lambda_1 = 1, \lambda_2 = 2, \lambda_3 = 3$ and the corresponding eigenvectors $x_1 = (-15, 12, 4)^T, x_2 = (-16, 13, 4)^T, x_3 = (-4, 3, 1)^T$.

Taking the approximations $\tilde{\lambda}_1 = 1.01, \tilde{x}_1 = (-15.01, 11.99, 3.99)^T$, $\tilde{\lambda}_2 = 1.99, \tilde{x}_2 = (-15.99, 13.01, 4.01)^T$ and $\tilde{\lambda}_3 = 3.01, \tilde{x}_3 = (-4.01, 2.99, 0.99)^T$ as input for our test program we obtain the following output:

[  1.000000000000000E+000,  1.000000000000000E+000 ]
[ -7.500000000000002E-001, -7.499999999999998E-001 ]
[ -2.500000000000001E-001, -2.499999999999999E-001 ]

another eigenvalue ? (y/n) n
 N ? (End = 0) 0
```

We see that the greatest component of each eigenvector is normalized to one and all enclosures are highly accurate. In fact they are 1 ulp intervals in the internal binary representation and they are only widened somewhat by the directed rounding of the binary to decimal conversion during output.

# 3.2 The General Eigenvalue Problem $Ax = \lambda Bx$

## 3.2.1 Introduction

The general eigenvalue problem (3.2) with two matrices $n \times n$-matrices $A$ and $B$ is often considered only for the case of symmetric $A$ and symmetric and positive definite $B$ only. In this case it is guaranteed that there are $n$ eigenvalues (not necessarily distinct) with corresponding eigenvectors.

In the case of arbitrary matrices $A$ and $B$ there may be more or less than $n$ eigenvalues as can be seen from the following simple $2 \times 2$-examples.

$$\begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix} x = \lambda \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} x$$

has only one simple eigenvalue, $\lambda = 3$ with eigenvector $x = \begin{pmatrix} -2 \\ 1 \end{pmatrix}$.

For

$$\begin{pmatrix} 1 & 2 \\ 0 & 0 \end{pmatrix} x = \lambda \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} x$$

all $\lambda \in \mathbb{R}$ are eigenvalues, the corresponding eigenvectors are $x = \begin{pmatrix} \lambda - 2 \\ 1 \end{pmatrix}$.

The other extreme is

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} x = \lambda \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} x$$

which has no eigenvalues at all.

Nevertheless, we will allow $A$ and $B$ to be arbitrary $n \times n$-matrices since the method which we will apply does not need additional hypotheses. It is a slight modification of the method of the previous Section 3.1 and is again only suited for the enclosure of simple eigenvalue/eigenvector pairs.

As for the ordinary eigenvalue problem we seek the solutions as zeros of the quadratic function

$$f(x, \lambda) := \begin{pmatrix} Ax - \lambda Bx \\ e_k^T x - 1 \end{pmatrix} \tag{3.11}$$

## 3.2.2 Theoretical Background

Since the theory of the method is practically identical to the case of the ordinary eigenvalue problem we will only sketch it briefly. Basically we can copy everything from Section 3.1.2 and replace the identity matrix $I$ in $Ax = \lambda Ix$ by the matrix $B$.

First we get the following reformulation of (3.11)

$$\begin{aligned} f(x,\lambda) &= f(\tilde{x}+y, \tilde{\lambda}+\mu) \\ &= \begin{pmatrix} A(\tilde{x}+y) - (\tilde{\lambda}+\mu)B(\tilde{x}+y) \\ e_k^T(\tilde{x}+y) - 1 \end{pmatrix} \\ &= \begin{pmatrix} A\tilde{x} - \tilde{\lambda}B\tilde{x} \\ e_k^T\tilde{x} - 1 \end{pmatrix} + \begin{pmatrix} Ay - \tilde{\lambda}By - \mu B(\tilde{x}+y) \\ e_k^T y \end{pmatrix} \\ &= f(\tilde{x},\tilde{\lambda}) + \begin{pmatrix} A - \tilde{\lambda}B & -B(\tilde{x}+y) \\ e_k^T & 0 \end{pmatrix} \begin{pmatrix} y \\ \mu \end{pmatrix} \end{aligned}$$

from which we again obtain a fixed point form

$$\begin{pmatrix} y \\ \mu \end{pmatrix} = g(y,\mu) \ . \tag{3.12}$$

with the function

$$g(y,\mu) = -Cf(\tilde{x},\tilde{\lambda}) + (I_{n+1} - C \begin{pmatrix} A - \tilde{\lambda}B & -B(\tilde{x}+y) \\ e_k^T & 0 \end{pmatrix}) \begin{pmatrix} y \\ \mu \end{pmatrix} \ . \tag{3.13}$$

Now all details of the method work completely analogous to the case of the ordinary eigenvalue problem with one minor exception: In the function $f$ now, there appears a triple product, $\lambda Bx$, which can no longer be computed directly by use of a scalar product expression.

The only place in the algorithm where we must take care of this triple product is the computation of the defect of the approximate solution,

$$d = A\tilde{x} - \tilde{\lambda}B\tilde{x} \ .$$

For the floating-point approximations $\tilde{x}$ and $\tilde{\lambda}$, however, each component of the product $\tilde{\lambda}\tilde{x}$ has at most a double length mantissa and thus this vector can be split *without roundoff-error* into the sum of two floating-point vectors $x_1$ and $x_2$:

$$x_1 + x_2 = \tilde{\lambda}\tilde{x} \ .$$

Now the defect $d$ can be rewritten as follows:

$$d = A\tilde{x} - Bx_1 - Bx_2$$

and this is again a scalar product expression which can be evaluated exactly (or with one rounding only) in PASCAL-XSC.

This modification of the computation of $d$ and the replacement of the identity matrix $I$ by the matrix $B$ at the appropriate places are the only differences between the method for the general eigenvalue problem and the method in Section 3.1 for the ordinary eigenvalue problem.

### 3.2.3 Algorithms

Obviously the algorithm for the general eigenvalue problem is almost identical to the one in Section 3.1.3. The modified algorithm is as follows.

## Algorithm 3.2: Eig $(A, B, lam, rx, ilam, ix, errcode)$ {procedure}

{Enclosure of an eigenpair for the eigenvalue problem $Ax = \lambda Bx$}
**input:** real matrices $A, B$, real $lam$ (appr. eigenvalue), real vector $rx$ (appr. eigenvector)
**output:** interval $ilam$ (eigenvalue enclosure), interval vector $ix$ (eigenvector enclosure), integer $errcode$ (error indicator)

(a) initialize errcode :
$errcode := 0$

(b) compute approximate inverse :
$R := \begin{pmatrix} A - lam \cdot B & -B \cdot rx \\ e_k^T & 0 \end{pmatrix}$
$C := \mathrm{Minv}(R, errcode)$
**if** $errcode \neq 0$ **then** stop

(c) improve floating-point approximation :
$(rx_{old}, lam_{old}) := (rx, lam)$
**repeat**
$(rx, lam) := (rx, lam) - C \cdot (A \cdot rx_{old} - lam_{old} \cdot B \cdot rx_{old}, e_k \cdot rx_{old} - 1)$
**until** $(rx, lam)$ accurate enough **or** max. iteration count exceeded

(d) compute enclosure of defect of floating-point approximation :
$rx_1 + rx_2 := lam \cdot rx$ { split double-length product in sum of two reals }
$D := -C \cdot \begin{pmatrix} \diamondsuit(A \cdot rx - B \cdot rx_1 - B \cdot rx_2) \\ 0 \end{pmatrix}$

(e) perform interval iteration :
$Z := D$ { starting vector }
$M := \mathrm{id}(C) - C \cdot \begin{pmatrix} \diamondsuit(A - lam \cdot B) & -B \cdot rx \\ e_k^T & 0 \end{pmatrix}$ { iteration matrix }
**repeat**
{ compute last column of iteration matrix : }
$M_{*,n+1} := e_{n+1}^T - C \cdot \begin{pmatrix} -B \cdot rx - B \cdot Z_{1..n} \\ 0 \end{pmatrix}$
$Z_A := \mathrm{blow}(Z, \epsilon)$ { $\epsilon$-inflation }
$Z := D + M \cdot Z_A$
**until** $Z \subseteq \mathrm{int}(Z_A)$ **or** max. iteration count exceeded

(f) return result :
**if** $Z \subseteq \mathrm{int}(Z_A)$ **then**
$ilam := lam + Z_{n+1}$ { eigenvalue enclosure }
$ix := rx + Z_{1..n}$ { eigenvector enclosure }
**else**
$errcode := 1$

(g) **return** $ilam, ix, errcode$

### 3.2.4 PASCAL-XSC Program Code

As is obvious from the previous discussion the following module `geig` for the computation of enclosures of eigenvalue/eigenvector pairs for the general eigenvalue problem differs only at few places from the corresponding module `eig` in Section 3.1.4. Also the changes which have to be done to make the module work for the data types interval, complex or complex interval are almost literally the same as in Section 3.1.4.

```
MODULE geig;

USE  i_ari,mvi_ari,mv_ari,lss_aprx;

```

### 3.2.5 Test Results

We demonstrate the use of the module `geig` by the following short PASCAL-XSC program which reads in a matrix $A$ and eigenvalue and eigenvector approximations. Procedure `EIG` from the module `geig` is then used to enclose an eigenpair which is close to the given approximation. The approximations can be entered repeatedly until 'n' or 'N' is entered in procedure `main`. Then a new dimension $n$ and another matrix $A$ may be entered, otherwise the program stops (if $n \leq 0$ is entered).

```
PROGRAM geigtest;

USE i_ari,mv_ari,mvi_ari,geig;

PROCEDURE MAIN( N : INTEGER );

VAR ERR : INTEGER;
    A,B : RMATRIX[1..N,1..N];
    EV  : RVECTOR[1..N];
    EW  : REAL;
    IEV : IVECTOR[1..N];
    IEW : INTERVAL;
    OK  : BOOLEAN;
    C   : CHAR;

PROCEDURE WRITE_EW;
VAR J : INTEGER ;
BEGIN
   WRITELN;
   WRITELN('Eigenvalue  = ', IEW );
   WRITELN('Eigenvector = ', IEV );
END { WRITE_EW };

BEGIN
   WRITELN('A = '); READ(A);
   WRITELN('B = '); READ(B);

   REPEAT
      WRITE('Eigenvalue  approximation : ');  READ(EW);
      WRITE('Eigenvector approximation : ');  READ(EV);

      EIG( A,B,EW,EV,IEW,IEV,ERR );
      OK:= ERR=0;

      IF OK THEN  WRITE_EW  ELSE
      BEGIN
         WRITELN;
         WRITELN( 'Verification not succeeded. errcode = ', ERR );
      END;
```

```
      WRITELN;
      WRITE( 'another eigenvalue ? (y/n) ' );
      READLN; READ(C);

   UNTIL C IN ['N','n'];
END;

VAR N : INTEGER ;

BEGIN
   REPEAT
      WRITE(' N ? (End = 0) '); READ(N);
      IF N>0 THEN MAIN( N );
   UNTIL N<=0;
END.
```

As a first example we use the following two matrices $A$ and $B$ taken from [15] and [335].

$$A = \begin{pmatrix} 12 & 1 & -1 & 2 & 1 \\ 1 & 14 & 1 & -1 & 1 \\ -1 & 1 & 16 & -1 & 1 \\ 2 & -1 & -1 & 12 & -1 \\ 1 & 1 & 1 & -1 & 11 \end{pmatrix}, \quad B = \begin{pmatrix} 10 & 2 & 3 & 1 & 1 \\ 2 & 12 & 1 & 2 & 1 \\ 3 & 1 & 11 & 1 & -1 \\ 1 & 2 & 1 & 9 & 1 \\ 1 & 1 & -1 & 1 & 15 \end{pmatrix}$$

As approximation for $\lambda$ we take $\tilde{\lambda} = 2.31$ and for the eigenvector $\tilde{x} = (-0.20, 0.093, 0.24, -0.17, 0.063)^T$.

The test program then gives the following output:

```
 N ? (End = 0) 5
A =
12  1 -1  2  1
 1 14  1 -1  1
-1  1 16 -1  1
 2 -1 -1 12 -1
 1  1  1 -1 11
B =
10  2  3  1  1
 2 12  1  2  1
 3  1 11  1 -1
 1  2  1  9  1
 1  1 -1  1 15
Eigenvalue  approximation : 2.31
Eigenvector approximation : -0.20 0.093 0.24 -0.17 0.063

Eigenvalue  = [  2.310604321348129E+000,  2.310604321348130E+000 ]
Eigenvector =
[ -8.523647246539458E-001, -8.523647246539456E-001 ]
[  3.881806704921011E-001,  3.881806704921012E-001 ]
[  1.000000000000000E+000,  1.000000000000000E+000 ]
[ -6.932489643679560E-001, -6.932489643679558E-001 ]
[  2.626493909653151E-001,  2.626493909653152E-001 ]

another eigenvalue ? (y/n) n
 N ? (End = 0) 0
```

This result agrees with the enclosures given in [15] where only a 13 digit decimal arithmetic was used.

As a second example we demonstrate that our algorithm also works in the case where the matrix $B$ is singular. We take

$$A = \begin{pmatrix} 1 & 2 \\ 0 & 3 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} .$$

Since $B$ is singular the eigenvalue problem $Ax = \lambda Bx$ has only *one* eigenvalue $\lambda_1 = 3$ with the corresponding eigenvector $x_1 = (-2, 1)^T$. For the crude approximations $\tilde{\lambda}_1 = 3.5$ and $\tilde{x}_1 = (-2.5, 1.5)^T$ we get the following results:

```
 N ? (End = 0) 2
A =
1 2 0 3
B =
0 0 0 1
Eigenvalue  approximation : 3.5
Eigenvector approximation : -2.5 1.5

Eigenvalue  = [  2.999999999999999E+000,  3.000000000000001E+000 ]
Eigenvector =
[  1.000000000000000E+000,  1.000000000000000E+000 ]
[ -5.000000000000000E-001, -5.000000000000000E-001 ]

another eigenvalue ? (y/n) n
 N ? (End = 0) 0
```

Even if both matrices, $A$ and $B$ are singular the algorithm still works, as can be seen from this final example:

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} .$$

which has the only eigenvalue $\lambda_1 = 0$ with the corresponding eigenvector $x_1 = (0, 1)^T$. For $\tilde{\lambda}_1 = 0.5$ and $\tilde{x}_1 = (0.5, 1.5)^T$ we get the output:

```
 N ? (End = 0) 2
A =
1 0 0 0
B =
0 0 0 1
Eigenvalue  approximation : 0.5
Eigenvector approximation : 0.5 1.5

Eigenvalue  = [  0.000000000000000E+000,  0.000000000000000E+000 ]
Eigenvector =
[  0.000000000000000E+000,  0.000000000000000E+000 ]
[  1.000000000000000E+000,  1.000000000000000E+000 ]

another eigenvalue ? (y/n) n
 N ? (End = 0) 0
```

Thus the program gets the results even *exactly* in this case.

# 3.3 The Symmetric Eigenvalue Problem $Ax = \lambda x, A^T = A$

In this section we present a method which computes highly accurate enclosures for the eigenvalues of a symmetric real matrix $A = A^T$. This method consists of three basic steps. First we compute eigenvalue and eigenvector approximations (by the classical Jacobi method in our case). Second, using the matrix $T$ of the eigenvector approximations we compute an enclosure of the transformed matrix $A_1 = T^{-1}AT$ and third, for $A_1$ we use Gerschgorin's circle theorem to derive enclosing intervals for the eigenvalues. The eigenvector then can be enclosed by standard estimations, see e.g. [333]. Increased accuracy will be obtained by additional measures like a modification of Jacobi's method, reorthonormalizations of the eigenvector approximations and the use of the exact scalar product.

## 3.3.1 Introduction

It is well known that for the eigenvalue problem with a real, symmetric matrix

$$Ax = \lambda x, \quad A^X = A, \tag{3.14}$$

there exists a real orthogonal matrix $X$ (i.e. $X = X^H$) which transforms $A$ into a diagonal matrix $D$

$$D = X^{-1}AX \ .$$

The columns of $X$ are the eigenvectors and the diagonal elements of $D$ are the eigenvalues of $A$.

Therefore, if $T \approx X$ is an approximation of the eigensystem, then

$$A_1 = T^{-1}AT \ . \tag{3.15}$$

will be a nearly or strongly diagonal dominant matrix, depending on the quality of the approximation $T$.

We will use such an approximation to compute an enclosure $[A_1]$ of $A_1$ and then we will apply Gerschgorin's circle theorem to $[A_1]$ to obtain safe enclosures of the eigenvalues of $A$.

The matrix $T$ may be computed by the well known Jacobi method, see [309] or [308]. For details on the enclosure method presented in this section see Lohner, [231].

## 3.3.2 Theoretical Background

Assume we have an approximate eigensystem $T$ of $A$ which was computed e.g. by the Jacobi method. Then we can get an enclosure of the transformed matrix $A_1$ from (3.15) by two different approaches.

First we can rewrite (3.15) as a linear matrix equation

$$TA_1 = AT$$

and can compute an enclosure for $A_1$ by the methods presented in Chapter 2. Here the product $AT$ has to be enclosed by an interval matrix, or the methods of Chapter 2 can be slightly modified to incorporate this product as a part of the enclosure method (i.e. to allow scalar products in the right hand side of the linear system).

Second, since $T$ is almost orthogonal we can again use the same procedure as in the case of the coordinate transformation with orthogonal matrices in Section 2.2.2.1. An enclosure $[T^{-1}]$ of $T^{-1}$ can thus be computed from (2.31) and we get

$$[A_1] = [T^{-1}](AT) \ .$$

Now, if $T$ was a sufficiently good approximate eigensystem, then $[A_1]$ is strongly diagonally dominant and we can apply Gerschgorin's circle theorem, [309], to obtain enclosures of the eigenvalues:

$$\lambda_i \in [\underline{a}_{ii} - \sum_{\substack{j=1 \\ i \neq j}}^{n} |[a_{ij}]|, \overline{a}_{ii} + \sum_{\substack{j=1 \\ i \neq j}}^{n} |[a_{ij}]|] \ .$$

The eigenvectors then can be enclosed by use of a standard estimation from Wilkinson, [333]. Let $\lambda$ be an exact eigenvalue and $\tilde{\lambda}$ its approximation. Furthermore let $x$ be the corresponding exact eigenvector, $\tilde{x}$ an approximation and both are assumed to be normalized in the Euklidian norm, $||x||_2 = ||\tilde{x}||_2 = 1$ with the residual norm $\epsilon = ||A\tilde{x} - \tilde{\lambda}\tilde{x}||_2$. Then

$$||x - \tilde{x}||_2^2 \leq \frac{\epsilon^2}{a^2} + \left[1 - (1 - \frac{\epsilon^2}{a^2})^{1/2}\right]^2 \tag{3.16}$$

where $a$ is the largest distance of $\tilde{\lambda}$ to the next eigenvalue, i.e. $\lambda$ and its approximation $\tilde{\lambda}$ are contained in $[\tilde{\lambda} - a, \tilde{\lambda} + a]$ and all the other eigenvalues are outside of this interval (and $a$ should be chosen as large as possible, of course ).

The PASCAL-XSC program in the following section does not compute eigenvector enclosures from this estimation. However, it computes further refinements of the eigenvalue enclosures. More details on these refinements can be found in Lohner, [231].

### 3.3.3 PASCAL-XSC Program Code

```
MODULE seig;

use i_ari,mv_ari,mvi_ari;

GLOBAL PROCEDURE SEIG( VAR A0 : RMATRIX;
                       VAR EW : IVECTOR; VAR ERRCODE : INTEGER );
{ SEIG computes enclosures for all eigenvalues of the symmetric matrix A0  }
{ A0 is the symmetric matrix (input parameter), symmetry is not checked !  }
```

```
{ EW is the output vector of the eigenvalue enclosures (in unsorted order) }
{ ERRCODE is an error indicator (always = 0 in this version of SEIG)       }

### 3.3.4 Test Results

We demonstrate the use of the module `seig` by the following short PASCAL-XSC program which computes the eigenvalues of a modified Zielke matrix. This $n \times n$-matrix $A$ depends on three parameters $a, b$ and $c$ and has the form:

$$A = \begin{pmatrix} a+b & a+b & \cdot & \cdot & a+b & a \\ a+b & \cdot & \cdot & a+b & a & \cdot \\ \cdot & \cdot & \cdot & a & \cdot & \cdot \\ \cdot & a+b & \cdot & \cdot & \cdot & \cdot \\ a+b & a & \cdot & \cdot & \cdot & a \\ a & \cdot & \cdot & \cdot & a & a-c \end{pmatrix}.$$

If $b$ and $c$ are very small compared to $a$ then $A$ has one large eigenvalue $\lambda_1 \approx na$ and the other ones are clustered in the order of magnitude of $b$ and $c$. If $b = c$, however, then one of the eigenvalues becomes extremely small as can be seen from the output of the following PASCAL-XSC program:

```
PROGRAM seigtest;

USE i_ari,mv_ari,mvi_ari,seig;

PROCEDURE MAIN( N : INTEGER );

VAR ERR,i,j : INTEGER;
    a,b,c   : REAL;
    A0      : RMATRIX[1..N,1..N];
    IEW     : IVECTOR[1..N];
BEGIN
   WRITE('a,b,c = '); READ(a,b,c);
   FOR i:= 1 TO N DO
   FOR j:= 1 TO N DO
       IF i+j <= N THEN A0[i,j]:= a + b
                   ELSE A0[i,j]:= a;
   A0[N,N]:= a - c;

   SEIG( A0,IEW,ERR );
```

```
   WRITELN('Eigenvalues :');
   FOR i:= 1 TO N DO WRITELN( i:3, ': ', IEW[i] );
END;

VAR N : INTEGER ;

BEGIN
   WRITELN('Eigenvalues of a modified Zielke matrix:');
   REPEAT
      WRITE(' N ? (End = 0) '); READ(N);
      IF N>0 THEN MAIN( N );
   UNTIL N<=0;
END.
```

If we choose $n = 4, a = 1E12, b = c = 1$ then we get the output:

```
Eigenvalues of a modified Zielke matrix:
 N ? (End = 0) 4
a,b,c = 1e12 1 1
Eigenvalues :
  1: [  4.000000000001250E+012,  4.000000000001251E+012 ]
  2: [  5.930703308172123E-001,  5.930703308172125E-001 ]
  3: [ -8.430703308172594E-001, -8.430703308172592E-001 ]
  4: [         -5.0000003E-013,         -4.9999997E-013 ]
 N ? (End = 0) 0
```

whereas for $n = 4, a = 1E12, b = 1, c = 0$ the smalles eigenvalues disappears:

```
Eigenvalues of a modified Zielke matrix:
a,b,c = 1e12 1 0
Eigenvalues :
  1: [  4.000000000001500E+012,  4.000000000001501E+012 ]
  2: [  7.071067811863340E-001,  7.071067811863342E-001 ]
  3: [ -7.071067811865843E-001, -7.071067811865840E-001 ]
  4: [  4.999999999999374E-001,  4.999999999999376E-001 ]
 N ? (End = 0) 0
```

The same occurs for higher dimensions of $A$: with $n = 12$ and the two parameter combinations as above we get:

```
Eigenvalues of a modified Zielke matrix:
 N ? (End = 0) 12
a,b,c = 1e12 1 1
Eigenvalues :
  1: [  1.200000000000541E+013,  1.200000000000542E+013 ]

```

It is amazing that in the case $c = 0$ the eigenvalues are almost symmetric to zero (all but the smallest and biggest one) but this symmetry is disturbed in the last few digits.

In the previous examples the matrices $A$ could be represented exactly in the binary floating-point system of the computer since they had only integer entries. We now modify these matrices by multiplying them with a factor of $10^{-12}$. Then of course the eigenvalues will be multiplied by the same factor, i.e. they will be unchanged in their (decimal) mantissa, only the exponent is decreased by 12.

However, these modified matrices are no longer representable exactly in the computer. Thus the program will compute eigenvalues of slightly perturbed matrices, the perturbation resulting *only* from rounding the input matrices to the floating-point screen. Still, however, this can have dramatic effects in the change of the eigenvalues. The results are contained in the following output:

```
Eigenvalues of a modified Zielke matrix:

# Chapter 4

# Evaluation of Polynomials in Several Variables

A widely used method for the numerical computation of the value of a polynomial in several variables is the nested Horner scheme. It is well known that even in the case of a polynomial in one variable, the computed values using Horner's scheme may be far from the correct values of the polynomial. This is especially true for polynomials in several variables.

In case of a polynomial in two variables

$$p(x,y) = \sum_{j=0}^{m}\sum_{i=0}^{n} a_{ij}x^i y^j = \sum_{j=0}^{m}(\sum_{i=0}^{n} a_{ij}x^i)y^j = \sum_{i=0}^{n}(\sum_{j=0}^{m} a_{ij}y^j)x^i$$

two variants of the nested Horner scheme, which are mathematically equivalent, are obvious. The first variant interprets $p(x,y)$ as a one-dimensional polynomial in $y$, the coefficients of which are one-dimensional polynomials in $x$. In the second version, $p(x,y)$ is considered to be a one-dimensional polynomial in $x$ with coefficients which are one-dimensional polynomials in $y$. For

$$p(x,y) = x^6 + 3x^5y - 5x^3y^3 + 3xy^5 - y^6 \tag{4.1}$$

this leads to

$$p(x,y) = (((-y+3x)y^2 - 5x^3)y^2 + 3x^5)y + x^6 \tag{4.2}$$

as the first variant and to

$$p(x,y) = (((x+3y)x^2 - 5y^3)x^2 + 3y^5)x - y^6 \tag{4.3}$$

as the second. Using a hexadecimal arithmetic with 14 mantissa digits (IBM\370), one obtains

$$\tilde{p}(4181,6765) \quad = \quad 1048576$$

in case (4.2) and

$$\tilde{p}(4181,6765) \quad = \quad 0$$

in case (4.3). $\tilde{p}$ means the machine evaluation of $p$. Indeed the correct value is $p(4181,6765) = 1$.

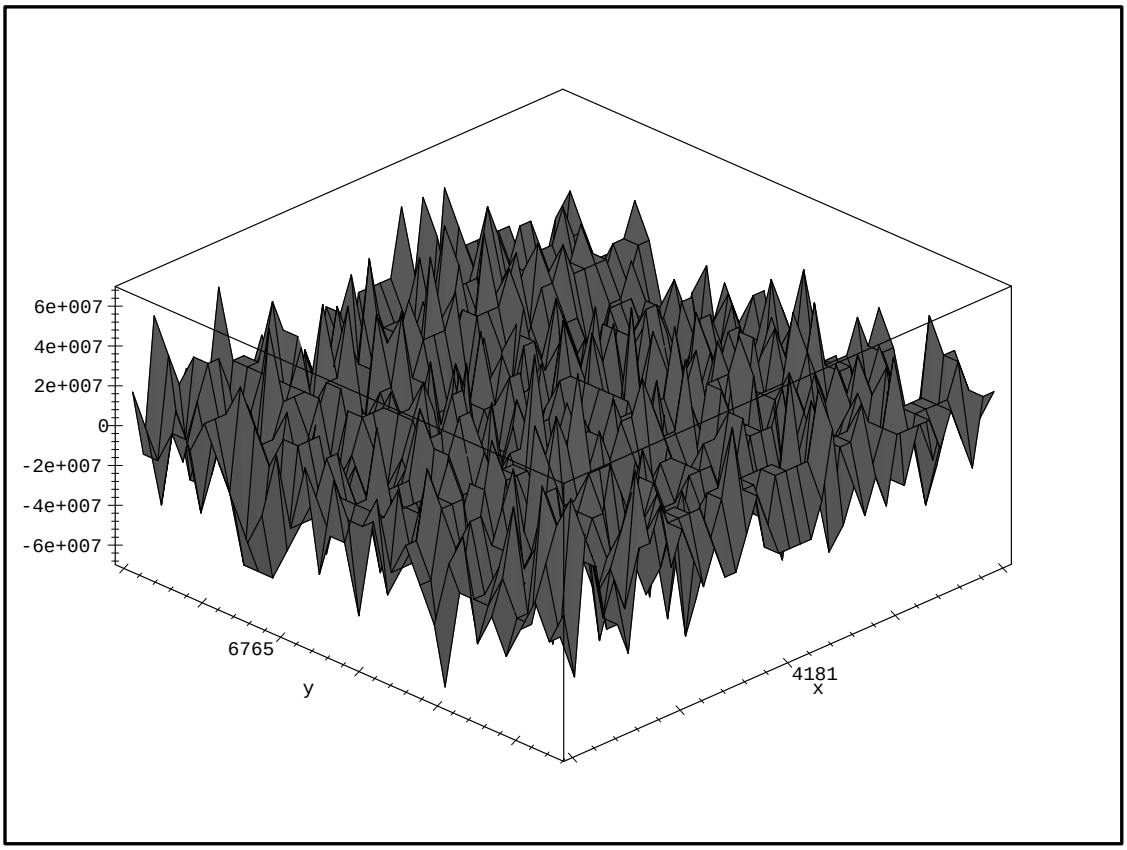

Figure 4.1: Rounding Errors in the Computation of Polynomial (4.1)

The question arises how such catastrophic errors may be overcome. The algorithm of Böhm [60, 61] to compute the value of one-dimensional polynomials with maximum accuracy is based on a transformation of the polynomial into an equivalent system of linear equations. Such a system can be solved with maximum accuracy using the residual iteration technique. To compute the value of a polynomial in several variables, a modified version of the algorithm given by Böhm is used by Lohner [230]. This algorithm does not only allow floating-point, but also so-called staggered interval coefficients (a sort of multiple-precision intervals) [190, 233]. The desired value of the (one-dimensional) polynomial is included in a staggered interval with a required accuracy. This algorithm is used repeatedly to compute intermediate results with increased accuracy as they occur in the nested Horner's scheme. The specification of an appropriate accuracy for the staggered formats at each level of the nested scheme leads to a final result with high accuracy.

## 4.1 Mathematical Background

In the following a different approach is used. The original idea of Böhm is the transformation of a one-dimensional polynomial into an equivalent system of linear

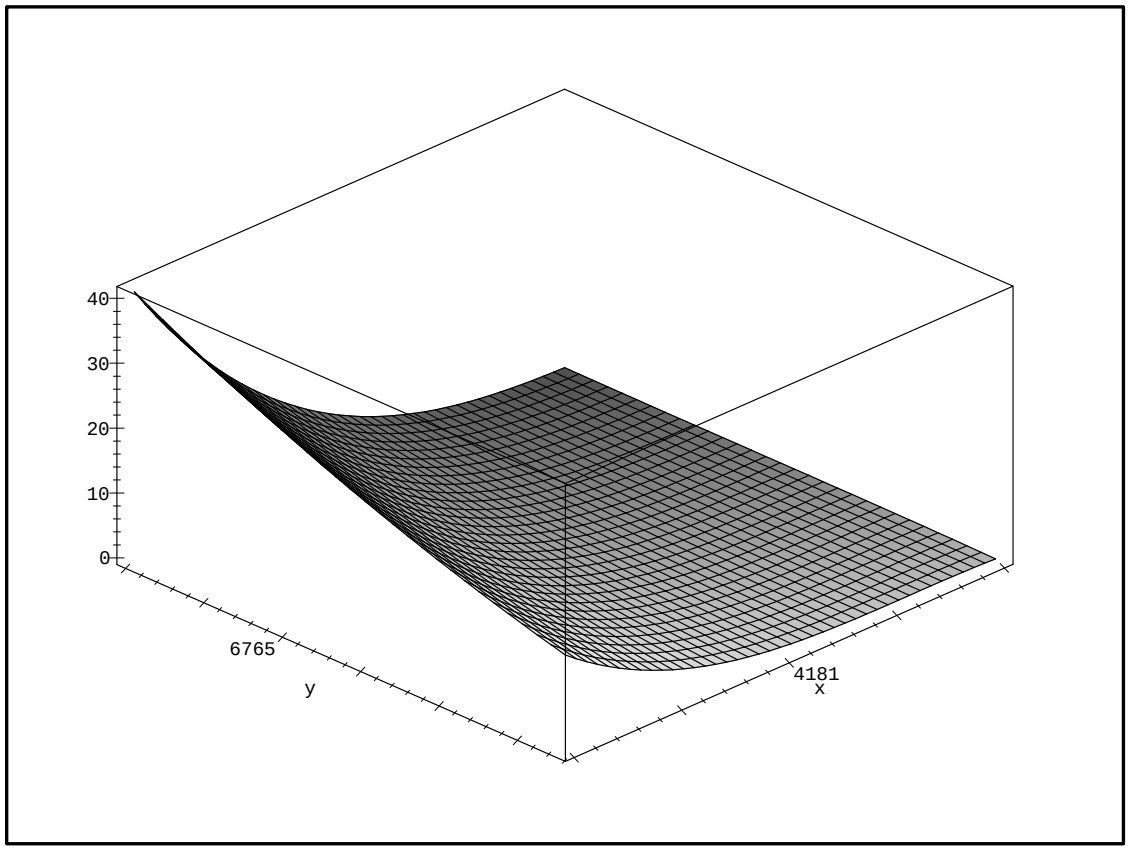

Figure 4.2: Polynomial (4.1) Without Rounding Errors

equations by introducing auxiliary variables for all intermediate results occurring in Horner's scheme. The same steps may be performed for polynomials in several variables [192]. This is illustrated by the following example. The polynomial

$$\begin{aligned} p(x,y) &= \sum_{j=0}^{3}(\sum_{i=0}^{2} a_{ij}x^i)y^j \\ &= \{\{\overbrace{[(a_{23}x + a_{13})x + a_{03}]}^{b_3(x)} \cdot y + \overbrace{[(a_{22}x + a_{12})x + a_{02}]}^{b_2(x)}\} \cdot y \\ &\quad \overbrace{[(a_{21}x + a_{11})x + a_{01}]}^{b_1(x)}\} \cdot y + \overbrace{[(a_{20}x + a_{10})x + a_{00}]}^{b_0(x)} \end{aligned} \tag{4.4}$$

is considered. Using auxiliary variables $x_i$ for all intermediate results, one obtains

$$\left.\begin{aligned}
x_1 &= a_{23} \\
x_2 &= x_1 \cdot x + a_{13} \\
x_3 &= x_2 \cdot x + a_{03} \\
x_4 &= a_{22} \\
x_5 &= x_4 \cdot x + a_{12} \\
x_6 &= x_3 \cdot y + x_5 \cdot x + a_{02} \\
x_7 &= a_{21} \\
x_8 &= x_7 \cdot x + a_{11} \\
x_9 &= x_6 \cdot y + x_8 \cdot x + a_{01} \\
x_{10} &= a_{20} \\
x_{11} &= x_{10} \cdot x + a_{10} \\
x_{12} &= x_9 \cdot y + x_{11} \cdot x + a_{00} \\
&= p(x,y)
\end{aligned}\right\} \text{ equivalently } \left\{\begin{aligned}
x_1 &= a_{23} \\
-x_1 \cdot x + x_2 &= a_{13} \\
-x_2 \cdot x + x_3 &= a_{03} \\
x_4 &= a_{22} \\
-x_4 \cdot x + x_5 &= a_{12} \\
-x_3 \cdot y - x_5 \cdot x + x_6 &= a_{02} \\
x_7 &= a_{21} \\
-x_7 \cdot x + x_8 &= a_{11} \\
-x_6 \cdot y - x_8 \cdot x + x_9 &= a_{01} \\
x_{10} &= a_{20} \\
-x_{10} \cdot x + x_{11} &= a_{10} \\
-x_9 \cdot y - x_{11} \cdot x + x_{12} &= a_{00}
\end{aligned}\right.$$

## 4.2 The Problem in Matrix-Vector Notation

In matrix-vector notation, this means that a system $A \cdot x = b$ must be solved. In the general case of a polynomial of degree $n$ in $x$ and degree $m$ in $y$ , one obtains

$$\underbrace{\begin{pmatrix} B & & & & \\ -Y & B & & & 0 \\ & \ddots & \ddots & & \\ & & \ddots & \ddots & \\ 0 & & & -Y & B \end{pmatrix}}_{A} \cdot \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ \vdots \\ x_{dim} \end{pmatrix} = \underbrace{\begin{pmatrix} a_{n\,m} \\ a_{n-1\,m} \\ \vdots \\ \vdots \\ a_{0\,0} \end{pmatrix}}_{b}$$

with

$$B = \underbrace{\begin{pmatrix} 1 & & & & \\ -x & 1 & & & 0 \\ & \ddots & \ddots & & \\ & & \ddots & \ddots & \\ 0 & & & -x & 1 \end{pmatrix}}_{n+1} \quad \text{and} \quad Y = \underbrace{\begin{pmatrix} 0 & \dots & & 0 \\ \vdots & 0 & & \vdots \\ \vdots & & 0 & 0 \\ 0 & \dots & 0 & y \end{pmatrix}}_{n+1} .$$

This is a system of linear equations with a very special lower triangular sparse matrix of dimension $dim = (m+1) \cdot (n+1)$. The last component of the solution vector is the value of the polynomial. The diagonal elements of the matrix $A$ are all 1 and the off-diagonal elements are the components of the point at which the polynomial is to be evaluated, with negative sign. The matrix does not depend on the polynomial coefficients. It is determined by the number of variables of the polynomial along with the maximum degree of each of these variables, and by the

point at which the polynomial is evaluated. The right-hand side $b$ of the system is given by the coefficients of the polynomial.

Let $A^{(r-1)} =: D$ be the matrix corresponding to the $r-1$ dimensional polynomial $p(t_1, t_2, \cdots, t_{r-1})$. The system corresponding to the $r$-dimensional problem is then given by

$$\underbrace{\begin{pmatrix} D & & & & \\ -X_r & D & & & \\ \ddots & \ddots & & & \\ & \ddots & \ddots & & \\ & & & -X_r & D \end{pmatrix}}_{A^{(r)}} \cdot \begin{pmatrix} x_1 \\ \vdots \\ \vdots \\ \vdots \\ x_{dim} \end{pmatrix} = \underbrace{\begin{pmatrix} a_{n_1 n_2 \ldots n_r} \\ \vdots \\ \vdots \\ \vdots \\ a_{00\ldots0} \end{pmatrix}}_{b^{(r)}} \quad . \tag{4.5}$$

The sparse lower triangular matrix $A^{(r)}$ corresponding to the polynomial

$$p(t_1, t_2, \cdots, t_r) = \sum_{i_r=0}^{n_r} \cdots \sum_{i_2=0}^{n_2} \sum_{i_1=0}^{n_1} a_{i_1, i_2, \cdots, i_r} t_1^{i_1} t_2^{i_2} \cdots t_r^{i_r} \tag{4.6}$$

consists of

$$dim = \prod_{k=1}^{r} (n_k + 1)$$

rows. Only the values 1, $-t_1$, $-t_2$, $\cdots$, $-t_r$ appear as elements of $A^{(r)}$. Again the right hand side $b^{(r)}$ is given by the coefficients of the polynomial $a_{i_1, i_2, \cdots, i_r}$ . They are ordered in such a way that the indices to the left are decreasing more rapidly. The value of the last component $x_{dim}$ of the solution $x$ of the system is the value $p(t_1, t_2, \cdots, t_r) = x_{dim}$ of the polynomial. $X_r$ is the $(n_{r-1}+1)(n_{r-2}+1)\cdots(n_1+1)$ dimensional matrix

$$X_r = \begin{pmatrix} 0 & \cdots & 0 & 0 \\ \vdots & & \vdots & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & t_r \end{pmatrix} \quad , \text{ with } \; t_r \text{ being the rightmost variable.}$$

The structure of the matrix $A^{(r)}$ may be expressed as follows: If a variable $x_k$ appears in some row of $A^{(r)}$, the distance $dist_k$ from the diagonal element of this row is always the same constant value given by:

$$\left.\begin{array}{lcl} dist_1 & := & 1, \\ dist_{k+1} & := & dist_k \cdot (n_k + 1), \quad k = 1, 2, \ldots, r \; . \end{array}\right\} \tag{4.7}$$

All diagonal elements of $A^{(r)}$ are 1. The value $-t_k$ appears in the $i-$th row of the matrix $A^{(r)}$ if and only if

$$i \equiv 0 \bmod dist_k \quad \text{and} \quad i \not\equiv dist_k \bmod dist_{k+1} \tag{4.8}$$

Here, the indices vary in the ranges $i = 1, 2, \ldots, dim$, $k = 1, 2, \ldots, r$. All other elements of the sparse matrix are 0.

The whole information of the problem is encoded in this system of linear equations. If the point of evaluation and the original coefficients of the polynomial are floating-point numbers, then the system is exactly representable on the computer.

The following figure shows the structure of the matrix corresponding to a three-dimensional polynomial

$$\begin{aligned} p(x,y,z) \;=\; & x^2y^3z^2 - 1.0y^3z^2 - 2.0x^2z^2 + 2.0z^2 + 1.0x^2y^3z^1 - 1.0y^3z^1 \\ & -2.0x^2z^1 + 2.0z^1 - 2.0x^2y^3 + 2.0y^3 + 4.0x^2 - 4321.0 \end{aligned} \tag{4.9}$$

with maximum degree $n_1 = 2$ in $x$, $n_2 = 3$ in $y$, and maximum degree $n_3 = 2$ in $z$. The indices given to the right of each row of the matrix are the indices of the coefficient of the polynomial that occurs at the corresponding position of the right hand side. The values of the coefficients not equal to zero are listed in the rigthmost column. Notice, that the matrix is never build up explicitely during program execution.

**Matrix structure:**

```
1.....  2 3 2   1.000
x1....  1 3 2
.x1...  0 3 2  -1.000
...1..  2 2 2
...x1.  1 2 2
..y.x1  0 2 2
......  2 1 2
......  1 1 2
.....y  0 1 2
.....1  2 0 2  -2.000
.....x  1 0 2
.....y  0 0 2   2.000
.....1  2 3 1   1.000
.....x  1 3 1
.....x  0 3 1  -1.000
.....1  2 2 1
.....x  1 2 1
.....y  0 2 1
.....1  2 1 1
.....x  1 1 1
.....y  0 1 1
.....1  2 0 1  -2.000
.....x  1 0 1
.....y  0 0 1   2.000
.....1  2 3 0  -2.000
.....x  1 3 0
.....x  0 3 0   2.000
.....1  2 2 0
.....x  1 2 0
.....y  0 2 0
.....1  2 1 0
.....x  1 1 0
.....y  0 1 0
.....1  2 0 0   4.000
.....x  1 0 0
.....y  0 0 0   4321.000
```

In this case one has $dist_1 = 1$, $dist_2 = 3$, $dist_3 = 12$ and $dist_4 = 36 = dim$ (see (4.7)). The characters `x`, `y`, and `z` indicate the positions wehre the values $-x$, $-y$, and $-z$ occur as entries of the sparse matrix. The matrix structure shown corresponds to the polynomial $p(x, y, z)$ of Exercise 1.

## 4.3 Algorithmic Description

With the notation (see (4.5))

$$A := A^{(r)} \text{ and } b := b^{(r)}$$

the linear system $A \cdot x = b$ corresponding to the polynomial

$$p(t_1, t_2, \cdots, t_r) = \sum_{i_r=0}^{n_r} \cdots \sum_{i_2=0}^{n_2} \sum_{i_1=0}^{n_1} a_{i_1,i_2,\cdots,i_r} t_1^{i_1} t_2^{i_2} \cdots t_r^{i_r}$$

in $r$ variables is to be solved.

A first approximation of the solution of this system is computed by the nested Horner scheme. This is equivalent to a forward substitution step for the lower triangular system. This step may be coded in PASCAL-XSC as follows:

```
FUNCTION initial_approx( b   : PolVector;
                         pnt : ArgVector;
                         Dist: Intvector): rvector[1..Ub(b)];

{ Computation of a first approximation to the sparse system A*x = b }

VAR  i, k: integer;
     x   : rvector[1..Ub(b)];
BEGIN
  FOR i:= 1 TO Ub(b) DO        { Loop over all rows of the sparse system }
  BEGIN
    x[i]:= b[i];               { x[i] is to be computed                  }
   { Loop over all variables xk, k= 1, 2, ...,r: }
    FOR k:= 1 TO Ub(pnt) DO BEGIN
      IF occurrence(i, k, Dist) THEN
        x[i]:= x[ i-dist[k] ] * pnt[k] + x[i];     { typical Horner step }
    END;
  END;
  initial_approx:= x;             { x[dim] is an approximation to p(pnt) }
END;
```

The result of this function is a dynamic array with $dim$ components. The function `occurrence(i,k,dist)` checks whether the variable $t_k$ of the polynomial occurs in the $i$-th row of the matrix. Formula (4.8) is used for this check. The $r + 1$ components of the vector `dist` are defined according to (4.7).

The approximation is improved step by step using residual iteration [285] until the desired accuracy is reached for the last component of the solution vector, which is the value of the polynomial. The complete algorithm may be summarized as follows:

## Algorithm 4.1: MultiDimPolyEval () {procedure}

1. Floating-point computation:
   Compute an approximation $x^{(0)}$ with $A \cdot x^{(0)} \approx b$ using forward substitution
2. Interval iteration:
   $k := 0$
   **repeat**

   (a) Compute an inclusion of the actual defect:
   $k := k + 1$
   $[d]^{(k)} := \diamondsuit(b - \sum_{j=0}^{k-1} Ax^{(j)}), \quad \diamondsuit :$ rounding to an enclosing interval

   (b) Compute $A[x]^{(k)} = [d]^{(k)}$ (forward substitution to get $[x]^{(k)}$ ):
   **for** i:=1 **to** dim **do**

   $$[x]_i^{(k)} := \diamondsuit([d]_i^{(k)} - \sum_{j=0}^{i-1} A_{ij} \cdot [x]_j^{(k)})$$

   (c) Enclosure of the last component of $A^{-1} \cdot b$:
   $[y] := \diamondsuit([x]_{dim}^{(k)} + \sum_{j=1}^{k-1} x_{dim}^{(j)})$

   (d) $x^{(k)} := \mathrm{mid}([x]^{(k)})$ (prepare next iteration step)

   **until** $(\mathrm{diam}[y]) \leq 1ulp$ **or** $(k \geq k_{max})$

3. The following has been verified: $p(t_1, \ldots, t_r) \in [y]$

The notation $\mathrm{diam}[y] \leq 1ulp$ means that the bounds of the interval $[y]$ are either the same or two adjacent floating-point numbers.

The numerically critical step 2a) is the computation of the defect $[d]^{(k)}$. Therefore it is done using the optimal dot product. The following listing shows the PASCAL-XSC implementation for this step:

```
FUNCTION defect( x   : rmatrix;
                 b   : PolVector;
                 pnt : ArgVector;
                 iter: integer ): ivector[1..Ub(b)];

{ Interval enclosure of the defect with respect to the actual }
{ approximation for the solution of the system                 }

VAR  i, k, j    : integer;
     ActDegree : IntVector[1..Ub(pnt)];
     d         : ivector[1..Ub(b)];
     accu      : dotprecision;

BEGIN
```

```
  { loop over all rows of the sparse system }
  FOR i:= 1 TO Ub(b) DO BEGIN
    {                  0    1          iter   }
    {   d := b - A*( x  + x  + ... + x     )  }
    accu:= #( b[i] - FOR j:= 0 TO iter SUM( x[i,j] ) );
    FOR k:= 1 TO Ub(pnt) DO  { loop over all variables tk }
      IF occurrence(i, k, Dist) THEN { tk appears in actual row }
         accu:= #( accu + FOR j:=0 TO iter SUM(x[i-dist[k], j]*pnt[k]) );
    defect[i]:= ##( accu );
  END;
END;
```

The result of this function is a dynamic array with $dim$ interval components. The following holds:

$$defect = [d]^{(\mathrm{iter}+1)} = \diamondsuit(b - Ax^{(0)} - Ax^{(1)} - Ax^{(2)} - \cdots - Ax^{(\mathrm{iter})}).$$

The vector `x[*,j]` corresponds to the $j$-th improvement $x^{(j)}$ of the solution of the sparse system.

## 4.4 Implementation and Examples

### 4.4.1 PASCAL-XSC Program Code

### 4.4.2 Numerical Examples

First the polynomial in two variables

$$p(x,y) = -1.0y^6 + 3.0x^1y^5 - 5.0x^3y^3 + 3.0x^5y^1 + 1.0x^6$$

is considered. The sparse matrix structure corresponding to this polynomial is shown and the polynomial is evaluated at the points (4181,6765), (17711,28657) and (3,7).

```
Evaluation of the polynomial:

  P(x,y) =    - 1.0 y^6 + 3.0 x^1 y^5 - 5.0 x^3 y^3

               + 3.0 x^5 y^1 + 1.0 x^6

```

### 4.4.3 Input Procedures Using Data Files

A comfortable specification of a multidimensional polynomial is provided. In the first line of the data file the number of variables is given. In the second line the maximum degree of each variable is specified. The number of integer values given there correspondes to the number of variables of the polynomial. In the subsequent lines the coefficients not equal to zero are listed together with their corresponding degrees of the variables of the polynomial. The end of the data file is indicated by a constellation of actual degrees which is not valid (for example: negative degrees). Comments in the data file are skipped automatically. A typical input file specifying polynomial in several variables is shown. The polynomial specified here is the polynomial (4.1).

```

                   $    all remaining coefficients are zero
$-------------------------------------------------------------
```

## 4.5 Restrictions and Hints

The final algorithm takes advantage of the very special form of the system matrix. In fact, this lower triangular sparse matrix is never built up explicitly in the memory of the computer. An optimal scalar product [214] is essential to make the sparse system algorithm work numerically. To get verified bounds, interval arithmetic [13] is used. Programming languages like FORTRAN-SC[1] [141], PASCAL-XSC or C-XSC [175] offer these features and are therefore essential tools for an implementation of such an algorithm.

## 4.6 Exercises

**Exercise 1:**

Let us consider the following polynomial in three variables:

$$\begin{aligned} p(x,y,z) = x^2y^3z^2 &+ x^2y^3z - 2x^2y^3 - y^3z^2 - y^3z \\ &+ 2y^3 - 2x^2z^2 - 2x^2z + 4x^2 + 2z^2 + 2z + 4321 \end{aligned}$$

The data file for this polynomial is shown in Paragraph 4.4.3.
For arbitrary values $x$ and $y$

$$p(x,y,-2) = 4325$$

holds.

[1]FORTRAN-SC is now available as the IBM program product ACRITH-XSC (High Accuracy Arithmetic-Extended Scientific Computation, program number 5684-129).

Show that Horner's scheme (as implemented in the given module `polmod`) leads to

$$\begin{aligned} p(1234, 5678, -2) &\approx 4352 \\ p(3333, 5555, -2) &\approx 4608 \\ p(7777, 7777, -2) &\approx 8192 \\ p(12345, 6789, -2) &\approx 0 \end{aligned}$$

whereas the new algorithm always computes the exact value 4321.

**Exercise 2:**
Use Horner's scheme to compute approximations for the polynomial

$$q(x) = x^4 - 8x^3 + 24x^2 - 32x + 16 = (x-2)^4$$

for the arguments $x_1 := \mathrm{pred}(\square(1.99991))$ and $x_2 := \mathrm{succ}(\square(1.99991))$. Here $\square$ means rounding to the nearest IEEE double number. The functions pred and succ return the next floating point number which is smaller or larger than the actual argument. Show that for the first argument $x_1$ the magnitude of the approximation is wrong. For the second argument $x_2$ even the sign of the approximation is wrong. Compute the correct values using the sparse system algorithm. Compute also $q(\square 1.99991)$. How sensitive are the correct results with respect to different rounding modes for x = 1.99991?

## 4.7 References and Further Readings

A very similar algorithm can be derived for polynomials in several variables with complex coefficients [198]. An algorithm for computing sharp enclosures of polynomials with interval coefficients can be found in [102]. For more information about the computation of sharp enclosures of the range of interval polynomials consult the literature cited in [102].

# Chapter 5

# Automatic Differentiation

The computation of derivatives is a task which one encounters in numerical analysis very often. Whenever a Newton method is to be applied then the derivative or the Jacobian matrix of the functions involved in the problem must be computed somehow. Also optimization methods often use gradients or even Hesse matrices.

Many numerical textbooks consider it as difficult to compute such derivatives. Numerical libraries on computers usually put the burdon of supplying subroutines for derivatives to the user of these libraries. Alternatively, derivatives are often replaced by finite difference quotients which brings into play many unnecessary additional problems like truncation errors and cancellation errors. Because of these apparent difficulties many numerical textbooks do not even try to consider methods which need derivatives of even higher order, like methods based on Taylor expansions.

Sometimes the use of symbolic differentiation is recommended to produce expressions for the needed derivatives. Almost all computer algebra systems can be utilized for this purpose. Many of them have features which allow the derived expressions to be converted to the syntax of some programming language. However, the expressions for the derivatives obtained in this way are often extremely complex and therefore costly to evaluate and sometimes they may even be numerically unstable to evaluate.

For many years already there exist interesting and very efficient methods to compute derivative values *exactly* (if exact arithmetic is used) for a large class of functions, i.e. in principle all functions which can be programmed in a common programming language. These methods are known as *automatic differentiation* and were developed already since the 60's by e.g. Moore, [247], and later by Rall, [267] – [272], Griewank, [114], [115], Iri, [148], Corliss, [86], [87], Fischer, [101] – [104] and many others. Automatic differentiation is only now starting to be recognized as a very useful tool by a wider audience in the community of numerical analysts. An extensive bibliography compiled by G. Corliss is contained in [115].

The main difference between these methods and finite differences and symbolic differentiation is that automatic differentiation computes derivative *values* which are the *exact* values of the derivatives (if exact arithmetic is used in the computation). I.e. automatic differentiation is a numerical method just as finite differences but in contrast to the latter it produces *exact* results. On the other side symbolic differentiation also produces exact results, however, there *expressions* for the derivatives are calculated. Numerical *values* of the derivatives are then obtained by evaluating the expressions numerically for suitable parameters. This indirect way makes symbolic differentiation often much more costly. Automatic differentiation can be viewed as a

combination of symbolic differentiation and numerical evaluation performed simultaneously. I.e. the differentiation rules are applied to the given function but they are applied immediately to the numerical values not first to expressions. This is the reason why automatic differentiation is exact just as symbolic differentiation but at the same time more efficient.

Also, during the last years many variants of automatic differentiation have been developed which differ primarily in the order in which the differentiation rules are applied. We can mainly distinguish between two different types of methods which are called the *forward mode* and the *reverse mode* of automatic differentiation.

Historically the forward mode was used first whereas the reverse mode was developed later. For functions in several variables the reverse mode is usually very much faster than the forward mode, the difference being very drastic: for a function $f : \mathbb{R}^n \to \mathbb{R}$ the time for computing the gradient using the forward mode is proportional to $n$ times the time required for an evaluation of $f$. In contrast, for the reverse mode the time to compute the gradient is less than about 5 times the cost for an evaluation of $f$, see e.g. [114], [148], [101], [104]. Amazingly, this time ratio is *independent* of the dimension $n$ !

In Section 5.1 we will first discuss the one-dimensional case with higher derivatives, i.e. we present an automatic differentiation method for the computation of Taylor coefficients. This method is a forward method. In Section 5.2 we turn to the multidimensional case and discuss the implementation of the reverse mode for the computation of gradients. Finally, in Section 5.3 we discuss and implement a method for the fast computation of directional derivatives. This is a forward method again but it is as efficient as a reverse method.

## 5.1 Functions in One Variable, Taylor Coefficients

### 5.1.1 Introduction

The computation of high derivatives of a function is often considered to be a tedious and error-prone task which is the reason why there exist almost no numerical methods making use of high derivatives. Only the Taylor series method for the approximate solution of ordinary differential equations is sometimes mentioned in textbooks. However, this method is usually discarded immediately because it is considered to be far too expensive. Higher derivatives often occur also in remainder terms of various numerical approximation methods such as Taylor expansion, interpolation, numerical integration and the like.

In this section we show that the computation of such higher derivatives is indeed very easy and efficient and that even unknown intermediate values which often appear in remainder terms can be handled almost trivially by the use of interval arithmetic. Here the combination of automatic differentiation and interval arithmetic has a strong effect of synergy: Computing high derivatives efficiently and enclosing unknown intermediate points in intervals results in methods of a totally new quality. This combination makes it possible to estimate remainder terms rigor-

ously and thus to derive proofs automatically on a computer which were not possible earlier (or which were at least much more complicated).

### 5.1.2 Theoretical Background

To keep the presentation simple assume that $f : \mathbb{R} \to \mathbb{R}$ is an analytic function (we could as well require $f$ to be only sufficiently smooth). Then $f(t)$ can be expanded in a Taylor series around a point $t_0$

$$f(t) = \sum_{k=0}^{\infty} \frac{f^{(k)}(t_0)}{k!}(t - t_0)^k \ . \tag{5.1}$$

We introduce the following short notation for the Taylor coefficients $\frac{f^{(k)}(t_0)}{k!}$ of $f$ at the point of expansion $t = t_0$

$$(f)_k := \frac{f^{(k)}(t_0)}{k!} = \frac{1}{k!}\frac{d^k f(t_0)}{dt^k} \tag{5.2}$$

or

$$(f(t_0))_k := \frac{f^{(k)}(t_0)}{k!} = \frac{1}{k!}\frac{d^k f(t_0)}{dt^k} \tag{5.3}$$

if we want to focus on the point of expansion $t_0$. Using (5.2) we can rewrite (5.1) as

$$f(t) = \sum_{k=0}^{\infty} (f)_k (t - t_0)^k \ . \tag{5.4}$$

Now let us consider functions $f$ which are the composition of arithmetic operations and elementary functions. For functions of such a structure we can recursively determine the Taylor coefficients by applying appropriate rules for each single operation occurring in the expression for $f$.

Starting with the two trivial cases we state that for a constant function $f = c$

$$(c)_0 = c, \quad (c)_k = 0, \quad \text{for } k \geq 1 \tag{5.5}$$

and for the independent variable $f = t$

$$(t)_0 = t_0, \quad (t)_1 = 1, \quad (t)_k = 0, \quad \text{for } k \geq 2 \ . \tag{5.6}$$

From the rules for operating with power series we immediately see that for two functions $u(t)$ and $v(t)$ we have

$$\begin{aligned}
(u \pm v)_k &= (u)_k \pm (v)_k \\
(u \cdot v)_k &= \sum_{j=0}^{k} (u)_j (v)_{k-j} \left( = \sum_{j=0}^{k} (u)_{k-j} (v)_j \right) \quad \text{(Cauchy product)} \\
(u/v)_k &= \frac{1}{(v)_0}((u)_k - \sum_{j=1}^{k} (v)_j (u/v)_{k-j}) \ .
\end{aligned} \tag{5.7}$$

Here the rule for the quotient can easily be obtained as follows: write $w = u/v$, then $u = v \cdot w$ and the product rule from (5.7) gives

$$(u)_k = \sum_{j=0}^{k} (v)_j (w)_{k-j} = (v)_0 (w)_k + \sum_{j=1}^{k} (v)_j (w)_{k-j}$$

which must be solved for $(w)_k = (u/v)_k$ to obtain the quotient rule in (5.7).

Because of the two different versions of the product rule in (5.7) many of the formulas in the rest of this section can also be represented in several different ways.

With these rules (5.5) – (5.7) we are already in the position to compute any Taylor coefficient of any rational function in $t$. We just have to apply these rules recursively for each operation in $f$.

As for division we can derive a formula for the square root $w = \sqrt{u}$ by writing $w \cdot w = u$ and applying the product rule which gives, for $k \geq 1$,

$$\begin{aligned} (\sqrt{u})_k &= \frac{1}{2(\sqrt{u})_0}((u)_k - \sum_{j=1}^{k-1} (\sqrt{u})_j (\sqrt{u})_{k-j}) \\ &= \begin{cases} \dfrac{1}{2(\sqrt{u})_0}((u)_k - 2 \sum\limits_{j=1}^{(k-1)/2} (\sqrt{u})_j (\sqrt{u})_{k-j}), & \text{if } k \text{ odd} \\ \dfrac{1}{2(\sqrt{u})_0}((u)_k - 2 \sum\limits_{j=1}^{(k-2)/2} (\sqrt{u})_j (\sqrt{u})_{k-j} - (\sqrt{u})_{k/2}^2), & \text{if } k \text{ even} \end{cases} \end{aligned} \tag{5.8}$$

where the last form uses only about half as many operations as the form in the first line. Of course, $(\sqrt{u})_0 = \sqrt{(u)_0}$.

Also for the square function $w = u^2$ we can write down a more economical form than just that for multiplication:

$$(u^2)_k = \sum_{j=0}^{k} (u)_j (u)_{k-j} = \begin{cases} 2 \sum\limits_{j=0}^{(k-1)/2} (u)_j (u)_{k-j}, & \text{if } k \text{ odd} \\ 2 \sum\limits_{j=0}^{(k-2)/2} (u)_j (u)_{k-j} + (u)_{k/2}^2, & \text{if } k \text{ even} . \end{cases} \tag{5.9}$$

To find similar recursion formulas also for elementary functions, we need a further relationship between the Taylor coefficients of $f$ and its derivative $f'$. Differentiating (5.4) with respect to $t$ we get a series for $f'$:

$$f'(t) = \sum_{k=1}^{\infty} k (f)_k (t - t_0)^{k-1} = \sum_{k=0}^{\infty} (k+1)(f)_{k+1} (t - t_0)^k . \tag{5.10}$$

On the other hand, since $(f')_k = \frac{1}{k!}(f')^{(k)}(t_0)$ we have another series representation of $f'$ :

$$f'(t) = \sum_{k=0}^{\infty} (f')_k (t - t_0)^k . \tag{5.11}$$

Equating coefficients of these two representations yields

$$(f')_k = (k+1)(f)_{k+1} \quad \text{or} \quad (f)_{k+1} = \frac{1}{k+1}(f')_k . \tag{5.12}$$

This relationsship (5.12) is very important in deriving new recursion formulas for elementary functions and also for other applications like the Taylor series solution of ordinary differential equations.

E.g. to get a formula for the Taylor coefficients of $w = e^{u(t)}$ we differentiate $w$ once with respect to $t$ giving $w' = w \cdot u'$. An application of the product rule from (5.7) yields for $k \geq 1$

$$k(w)_k = (w')_{k-1} = (w \cdot u')_{k-1} = \sum_{j=0}^{k-1} (w)_j (u')_{k-1-j} = \sum_{j=0}^{k-1} (w)_j (k-j)(u)_{k-j}$$

and solving this for $(w)_k = (e^u)_k$ we get:

$$(e^u)_k = \frac{1}{k} \sum_{j=0}^{k-1} (k-j)(e^u)_j (u)_{k-j}, \quad k \geq 1 \tag{5.13}$$

and $(e^u)_0 = e^{(u)_0}$ for $k = 0$ since for any function $f$ we always have trivially

$$(f(u))_0 = f((u)_0) \ .$$

The recursion formulas in the rest of this section therefore are all valid for $k \geq 1$.

In a very similar way we can obtain formulas for the Taylor coefficients of $\sin u$ and $\cos u$:

$$\begin{aligned} (\sin u)_k &= \frac{1}{k} \sum_{j=0}^{k-1} (k-j)(\cos u)_j (u)_{k-j} \\ (\cos u)_k &= -\frac{1}{k} \sum_{j=0}^{k-1} (k-j)(\sin u)_j (u)_{k-j} \end{aligned} \tag{5.14}$$

and also for $\sinh u$ and $\cosh u$:

$$\begin{aligned} (\sinh u)_k &= \frac{1}{k} \sum_{j=0}^{k-1} (k-j)(\cosh u)_j (u)_{k-j} \\ (\cosh u)_k &= \frac{1}{k} \sum_{j=0}^{k-1} (k-j)(\sinh u)_j (u)_{k-j} \ . \end{aligned} \tag{5.15}$$

Obviously these formulas have to be applied pair-wise.

For the power function $w = u^a$ with a constant exponent $a$ we can use the same technique, i.e. from $w' = au^{a-1}u' = a\frac{u^a}{u}u'$ we get $w'u = awu'$ where again the product rule gives

$$(u^a)_k = \frac{1}{k\,(u)_0} \sum_{j=0}^{k-1} (a\,(k-j) - j)(u^a)_j (u)_{k-j} \tag{5.16}$$

Now, the recursion formulas of almost all the other elementary functions which we will include in our PASCAL-XSC program can be derived in the following way: assume $f = f(u(t))$ has a derivative of the form $f' = f'(u)u'$ with $f' = 1/g(u)$, i.e. $f' = u'/g$ where $g = g(u)$ is a function which can also be expressed in a form that enables us to compute its Taylor coefficients. Then $u' = f' \cdot g$ and

$$k(u)_k = (u')_{k-1} = (f'g)_{k-1} = \sum_{j=0}^{k-1} (f')_j (g)_{k-j-1} = \sum_{j=1}^{k} j (f)_j (g)_{k-j} \ . \tag{5.17}$$

Solving for $(f)_k$ yields

$$(f)_k = \frac{1}{(g)_0}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(f)_j(g)_{k-j}) \ . \tag{5.18}$$

Using this relation the Taylor coefficients of the remaining functions can be listed in the following table:

| $f$ | $g$ | $(f)_k$ |
|---|---|---|
| $\ln u$ | $u$ | $\frac{1}{(u)_0}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\ln u)_j(u)_{k-j})$ |
| $\tan u$ | $\cos^2 u$ | $\frac{1}{\cos^2(u)_0}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\tan u)_j(\cos^2 u)_{k-j})$ |
| $\cot u$ | $-\sin^2 u$ | $\frac{-1}{\sin^2(u)_0}((u)_k + \frac{1}{k}\sum_{j=1}^{k-1} j(\cot u)_j(\sin^2 u)_{k-j})$ |
| $\arcsin u$ | $\sqrt{1-u^2}$ | $\frac{1}{\sqrt{1-(u)_0^2}}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\arcsin u)_j(\sqrt{1-u^2})_{k-j})$ |
| $\arccos u$ | $-\sqrt{1-u^2}$ | $\frac{-1}{\sqrt{1-(u)_0^2}}((u)_k + \frac{1}{k}\sum_{j=1}^{k-1} j(\arccos u)_j(\sqrt{1-u^2})_{k-j})$ |
| $\arctan u$ | $1+u^2$ | $\frac{1}{1+(u)_0^2}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\arctan u)_j(1+u^2)_{k-j})$ |
| $\operatorname{arccot} u$ | $-(1+u^2)$ | $\frac{-1}{1+(u)_0^2}((u)_k + \frac{1}{k}\sum_{j=1}^{k-1} j(\operatorname{arccot} u)_j(1+u^2)_{k-j})$ |
| $\tanh u$ | $\cosh^2 u$ | $\frac{1}{\cosh^2(u)_0}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\tanh u)_j(\cosh^2 u)_{k-j})$ |
| $\coth u$ | $-\sinh^2 u$ | $\frac{-1}{\sinh^2(u)_0}((u)_k + \frac{1}{k}\sum_{j=1}^{k-1} j(\coth u)_j(\sinh^2 u)_{k-j})$ |
| $\operatorname{arsinh} u$ | $\sqrt{u^2+1}$ | $\frac{1}{\sqrt{(u)_0^2+1}}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\operatorname{arsinh} u)_j(\sqrt{u^2+1})_{k-j})$ |
| $\operatorname{arcosh} u$ | $\sqrt{u^2-1}$ | $\frac{1}{\sqrt{(u)_0^2-1}}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\operatorname{arcosh} u)_j(\sqrt{u^2-1})_{k-j})$ |
| $\operatorname{artanh} u$ | $1-u^2$ | $\frac{1}{1-(u)_0^2}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\operatorname{artanh} u)_j(1-u^2)_{k-j})$ |
| $\operatorname{arcoth} u$ | $1-u^2$ | $\frac{1}{1-(u)_0^2}((u)_k - \frac{1}{k}\sum_{j=1}^{k-1} j(\operatorname{arcoth} u)_j(1-u^2)_{k-j})$ |

Table 4.1: Table of Taylor coefficients

In PASCAL-XSC there are also some exponential and logarithmic functions for special bases ( 2 and 10 ), for which we give the recursion formulas here, which are

easily deduced from the above ones:

$$
\begin{aligned}
(2^u)_k &= \frac{\ln 2}{k} \sum_{j=0}^{k-1} (k-j)(2^u)_j (u)_{k-j} \\
(10^u)_k &= \frac{\ln 10}{k} \sum_{j=0}^{k-1} (k-j)(10^u)_j (u)_{k-j} \\
({}_2\log u)_k &= \frac{1}{\ln 2} (\ln u)_k \\
({}_{10}\log u)_k &= \frac{1}{\ln 10} (\ln u)_k
\end{aligned}
$$

Finally, we mention that also simple formulas for differentiation and integration can be derived which are even essentially the same as formula (5.12). From term-wise differentiation and integration of a Taylor series we see immediately that:

$$
(\frac{du}{dt})_k = (k+1)(u)_{k+1}, \quad k \geq 0 \tag{5.19}
$$

and

$$
(\int_{t_0}^{t} u(s)ds)_0 = 0, \quad (\int_{t_0}^{t} u(s)ds)_k = \frac{(u)_{k-1}}{k}, \quad k \geq 1 \ . \tag{5.20}
$$

We do not include these two operations in our module for the computation of Taylor coefficients. The reason for this is that in this module we want to include only operations which for a given set of indices $k = 0, \ldots, p$, compute the exact values of the Taylor coefficients (or enclosures of these values on the computer) for *all* of these indices. However, with differentiation, we are no longer able to compute the $p$-th coefficient, since to do this we would need the $(p+1)$-st coefficient of the original function which is not supplied in the program when the max. order is $p$.

### 5.1.3 Algorithms

We implement the recursive computation of the Taylor coefficients as a so-called Taylor arithmetic. I.e. we introduce (p+1)-tupels $((u)_0, \ldots, (u)_p)$ containing the Taylor coefficients of $u$ up to the $p$-th order and define arithmetic operations and standard function for these tupels in such a way that the result-tupel of each operation contains the Taylor coefficients of the resulting function (up to the $p$-th order). In order to take the roundoff errors into account we use intervals for the representation of the Taylor coefficients such that we get guaranteed enclosures thereof.

For these $(p+1)$-tupels we use the PASCAL-XSC data type

```
TYPE  itaylor  = DYNAMIC ARRAY [*] OF INTERVAL;
```

The index range must always be $0, \ldots, p$, where $p \geq 0$ is some arbitrary integer which must be the same for all operands in a computation. However, none of the algorithms checks this condition, i.e. the algorithms may fail if they are used with operands of differing length.

We begin with the four basic operators $+, -, \cdot$ and $/$.

## Algorithm 5.1: $+\,(u, v)$ {operator}

{Computation of the Taylor coefficients for $u + v$}
**input:** *itaylor* $u$, $v$ of length $p + 1$
**output:** Enclosure of the Taylor coefficients of $u + v$ (operator result)

**for** $k := 0$ **to** $p$ **do** $w_k := u_k + v_k$
**return** $w$

## Algorithm 5.2: $-\,(u, v)$ {operator}

{Computation of the Taylor coefficients for $u - v$}
**input:** *itaylor* $u$, $v$ of length $p + 1$
**output:** Enclosure of the Taylor coefficients of $u - v$ (operator result)

**for** $k := 0$ **to** $p$ **do** $w_k := u_k - v_k$
**return** $w$

## Algorithm 5.3: $*\,(u, v)$ {operator}

{Computation of the Taylor coefficients for $u \cdot v$}
**input:** *itaylor* $u$, $v$ of length $p + 1$
**output:** Enclosure of the Taylor coefficients of $u \cdot v$ (operator result)

**for** $k := 0$ **to** $p$ **do** $w_k := \diamondsuit \sum_{j=0}^{k} u_j \cdot v_{k-j}$
**return** $w$

## Algorithm 5.4: $/\,(u, v)$ {operator}

{Computation of the Taylor coefficients for $u/v$}
**input:** *itaylor* $u$, $v$ of length $p + 1$
**output:** Enclosure of the Taylor coefficients of $u/v$ (operator result)

**for** $k := 0$ **to** $p$ **do** $w_k := \diamondsuit(u_k - \sum_{j=1}^{k} v_j \cdot w_{k-j})/v_0$
**return** $w$

Square, squareroot and exponential are formulated along (5.9, 5.8) and (5.13).

## Algorithm 5.5: Sqr $(u)$ {function}

{Computation of the Taylor coefficients for $u^2$ }
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosure of the Taylor coefficients of $u^2$ (function result)

$w_0 := u_0^2$
**for** $k := 1$ **to** $p$ **do** $m := (k+1)$ **div** $2$ {integer division}
$w_k := 2 \diamondsuit \sum_{j=0}^{m-1} u_j \cdot u_{k-j}$
**if not** odd$(k)$ **then** $w_k := w_k + u_m^2$
Sqr $:= w$

## Algorithm 5.6: Sqrt $(u)$ {function}

{Computation of the Taylor coefficients for $\sqrt{u}$ }
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosure of the Taylor coefficients of $\sqrt{u}$ (function result)

$w_0 := \sqrt{u_0}$
**for** $k := 1$ **to** $p$ **do** $m := (k+1)$ **div** $2$ {integer division}
$w_k := 2 \diamondsuit \sum_{j=1}^{m-1} w_j \cdot w_{k-j}$
**if not** odd$(k)$ **then** $w_k := w_k + w_m^2$
$w_k := (u_k - w_k)/(2 \cdot w_0)$
Sqrt $:= w$

## Algorithm 5.7: Exp $(u)$ {function}

{Computation of the Taylor coefficients for $e^u$ }
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosure of the Taylor coefficients of $e^u$ (function result)

$w_0 := \exp^{u_0}$
**for** $k := 1$ **to** $p$ **do** $w_k := (\sum_{j=0}^{k-1}(k-j) \cdot w_j \cdot u_{k-j})/k$
Exp $:= w$

The next algorithm implements the pair of formulas (5.14) for the sine- and cosine-functions. It returns the Taylor coefficients for both functions and can therefore be used for each, sine and cosine.

## Algorithm 5.8: Sin_Cos $(u, w\_sin, w\_cos)$ {procedure}

{Computation of the Taylor coefficients for $\sin u$ and $\cos u$ }
**input:** *itaylor* $u$ of length $p+1$
**output:** $w\_sin$, enclosures of the Taylor coefficients of $\sin u$ and
$w\_cos$, enclosures of the Taylor coefficients of $\cos u$

$w\_sin_0 := \sin(u_0)$
$w\_cos_0 := \cos(u_0)$
**for** $k := 1$ **to** $p$ **do** $w\_sin_k := (\sum_{j=0}^{k-1}(k-j)\cdot w\_cos_j \cdot u_{k-j})/k$
$w\_cos_k := -(\sum_{j=0}^{k-1}(k-j)\cdot w\_sin_j \cdot u_{k-j})/k$
**return** $w\_sin, w\_cos$

Thus we have the following two simple algorithms for the sine and the cosine functions:

## Algorithm 5.9: Sin $(u)$ {function}

{Computation of the Taylor coefficients for $\sin u$}
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosures of the Taylor coefficients of $\sin u$ (function result)

Sin_Cos $(u, w\_sin, w\_cos)$
Sin $:= w\_sin$

## Algorithm 5.10: Cos $(u)$ {function}

{Computation of the Taylor coefficients for $\cos u$}
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosures of the Taylor coefficients of $\cos u$ (function result)

Sin_Cos $(u, w\_sin, w\_cos)$
Cos $:= w\_cos$

Precisely the same algorithms 5.5.8 – 5.5.10 can also be used for the hyperbolic sine and cosine functions. Only the minus sign in the second line of the for-loop in algorithm 5.5.8 has to be discarded ( compare (5.14) and (5.15) ).

The last two algorithms are the one for the power function $u^a$ with constant exponent $a$,

## Algorithm 5.11: Power $(u)$ {function}

{Computation of the Taylor coefficients for $u^a$ }
**input:** *itaylor* $u$ of length $p+1$, *interval* $a$
**output:** Enclosure of the Taylor coefficients of $u^a$ (function result)

$w_0 := \text{power}(u_0, a)$
**for** $k := 1$ to **to** $p$ **do** $w_k := (\sum_{j=0}^{k-1}(a\cdot(k-j)-j)\cdot w_j \cdot u_{k-j})/(k\cdot u_0)$
Power $:= w$

and a generic algorithm for the remaining elementary functions, which implements (5.18) where for each specific function $w$ the corresponding function $g$ from Table 4.1 has to be inserted.

**Algorithm 5.12:** Function_f $(u)$ {function}

{Computation of the Taylor coefficients for a function $f(u)$ with $f' = u'/g$ }
**input:** *itaylor* $u$ of length $p+1$
**output:** Enclosure of the Taylor coefficients of $f(u)$ (function result)

{Compute Taylor coefficients of g, using the above algorithms}
$w_0 := f(u_0)$
**for** $k := 1$ **to** $p+1$ **do** $w_k := (u_k - (\sum_{j=1}^{k-1} j \cdot w_j \cdot g_{k-j})/k)/g_0$
Function_f $:= w$

## 5.1.4 PASCAL-XSC Program Code

Here we list the PASCAL-XSC module `itaylor` which implements the automatic computation of Taylor coefficients in interval arithmetic, i.e. with the operators and functions in this module we can compute guaranteed enclosures of Taylor coefficients. At the end of this section we indicate which changes have to be done in the module to adapt it to other data types.

```
MODULE itaylor;

USE GLOBAL i_ari;

{------------------------------------------------------------------------------}
{  This module itayor contains operators and functions for the recursive      }
{  computation of Taylor coefficients. These operators and functions are:     }
{    +, -(unary), +, -, *, /, sqr, sqrt, exp, exp2, exp10, ln, log2, log10,   }
{    power, sin, cos, tan, cot, arcsin, arccos, arctan, arccot,               }
{    sinh, cosh, tanh, coth, arsinh, arcosh, artanh, arcoth                   }
{------------------------------------------------------------------------------}
{  The data type for Taylor coefficients is a dynamic array of interval.      }
{  A variable of type itaylor represents the Taylor coeffcients, i.e.         }
{  u[0] = (u)_0, ..., u[n] = (u)_n; all operands are assumed to have the      }
{  same index range starting from 0. This is never checked however !          }
{------------------------------------------------------------------------------}

GLOBAL TYPE itaylor = GLOBAL DYNAMIC ARRAY [*] OF INTERVAL;

```

Concluding this section we mention that by only a few simple changes the module can be converted to a module rtaylor for the computation of Taylor coefficients using

the REAL data type, or to a module ctaylor using the COMPLEX data type or even to a module citaylor using the CINTERVAL data type ( i.e. complex intervals).

Apart from renaming the module the following changes should be made:

- change the `USE`-clause; no `USE` is necessary for REAL, `USE c_ari` is needed for COMPLEX and `USE i_ari,c_ari,ci_ari` are needed for CINTERVAL.
- change all occurences of the data type INTERVAL to REAL, COMPLEX or CINTERVAL as desired. Then also the name of the data type itaylor should be changed into rtaylor, ctaylor or citaylor.
- change the `##` prefixes of the scalar product expressions to `#*` and discard the calls to the intrinsic function INTVAL in the cases of REAL and COMPLEX. In these cases also replace INTERVAL by REAL for the variables `ln2` and `ln10` in the functions `exp2` and `exp10`.
- operators with mixed operand types (taylor, REAL, INTERVAL, COMPLEX and/or CINTERVAL) may be added or deleted as desired.

There are however versions of PASCAL-XSC where many complex standard functions are not implemented (and also not those for complex intervals). With these versions only the basic arithmetic will work in complex, the standard functions will not.

### 5.1.5 Test Results

**Example 5.1:**

As a first test for the module itaylor we write a simple program which defines a function $f$ using the type itaylor and evaluates it thereby using the operators and functions of the module. Thus the result is again an itaylor containing enclosures of the Taylor coefficients of $f$.

```
PROGRAM itseries;

USE itaylor;

{------------------------------------------------------------------------}
{ This program computes the Taylorpolynomial of a function f(x) up to    }
{ the term of p-th order using the operators and functions from          }
{ the module itaylor.                                                    }
{ The function f is defined as PASCAL-XSC function using the type itaylor. }
{------------------------------------------------------------------------}

FUNCTION f ( t : itaylor ) : itaylor[0..ub(t)];
BEGIN
   f:= exp( -sqr(t) )
END;

PROCEDURE main( p : INTEGER );
VAR k   : INTEGER;
```

```
    x,y : itaylor[0..p];
    x0  : INTERVAL;
BEGIN
   WRITE( 'point of expansion : ' );  READ ( x0 );
   expand( x, x0 );
   y:= f( x );
   FOR k:= 0 TO p DO  WRITELN( k:3,' :  ', y[k] );
END;

VAR p : INTEGER;

BEGIN
   REPEAT
      WRITE( 'order of Taylorpolynomial : ' ); READ ( p );
      IF p >= 0 THEN main ( p );
   UNTIL p < 0;
END.
```

If we enter 10 for the order of the Taylor polynomials and 0, 1 and 10 for the expansion points then the program produces the following output for the function $f(t) = e^{-t^2}$ (we have added the user's input for completeness; entering -1 for the order at the end stops the program):

```
order of Taylorpolynomial : 10
point of expansion : 0
  0 :  [  1.000000000000000E+000,  1.000000000000000E+000 ]

order of Taylorpolynomial : -1
```

It should be noted again that these numbers are *guaranteed enclosures* of the *exact* Taylor coefficients of the function $f$ in the program.

### Example 5.2:

In the second example we use the operations from the itaylor module plus an additional function `integral` which computes the Taylor coefficients of the integral $\int_{t_0}^{t} u(s)ds$ of a function $u(t)$ according to (5.20).

The program computes the Taylor polynomial of the solution of an initial value problem with a first order ordinary differential equation about the expansion point $t = t_0$ by use of Picard iteration. The initial value problem is

$$u'(t) = f(t, u(t)), \quad u(t_0) = u_0 \ . \tag{5.21}$$

Starting with a constant function $u_0(t) = u_0$ we compute $p$ iterations with the equivalent integral equation:

$$u_i(t) = u_0 + \int_{t_0}^{t} f(s, u_{i-1}(s))ds \ . \tag{5.22}$$

In this iteration the function $f$ is evaluated by use of the operators and functions from the module itaylor and the integral by (5.20). Thus the result of each iteration in the program is the Taylor polynomial of degree $p$ of the corresponding exact iterate. Since each iteration produces successively one additional term of the Taylor series of the solution $u(t)$ we have after $p$ iterations the exact Taylor polynomial of $u(t)$, i.e. from the program we get enclosures for the first $p$ coefficients of the Taylor series of the solution $u(t)$ of (5.21).

```
PROGRAM ode_series;

USE itaylor;

{------------------------------------------------------------------------}
{ This program computes an enclosure for the Taylorpolynomial of order p  }
{ of a function u(t) defined by a first order ode.                        }
{ For this purpose the operators and functions from the module itaylor    }

```

As in the previous example the enclosures are *guaranteed enclosures* of the *exact* Taylor coefficients of the solution $u(t)$, however, we should bear in mind that even the exact Taylor polynomial is still only an approximation of the true solution $u(t)$. To get an enclosure of the true solution on some interval $[t_0, t_0 + h]$ we must also compute an enclosure of the corresponding remainder term. This can again be done with the operations in the module itaylor, but to this end we need somewhat more theory since a stepsize $h$ and a first rough enclosure $[u^{(0)}]$ of $u$ on $[t_0, t_0 + h]$ must be computed. For details see e.g. [247], [248], [207], [228], [229], [232].

We should also note that the computation of the Taylor coefficients in this example can be organized more efficiently: In the $k$-th iteration the coefficients $(u)_0, \ldots, (u)_{k-1}$ of the exact solution $u(t)$ are known already and $(u)_{k+1}, \ldots (u)_p$ can not yet be computed. Therefore it is cheaper to compute *only* the $k$-th coefficient in the $k$-th iteration and not all $p$ coefficients which would mean that we unnecessarily recompute the coefficients with low indices and compute values for coefficients with high indices which are not yet the wanted exact Taylorcoefficients of $u$.

Further examples include problems where a guaranteed enclosure of a solution can be computed by use of a remainder term containing higher derivatives of a function at some unknown intermediate point of an interval. The enclosure of the solution of an initial value problem is such an example, another very important one is numerical quadrature. In Chapter 10 we will make intensive use of the module itaylor to enclose the remainder terms occuring there in order to compute enclosures for the values of definite integrals.

### 5.1.6 Notes and References

First we make some comments on the itaylor module and on possible variations and improvements thereof. The possible change of the data type interval to real, complex or complex interval has already been discussed in Section 5.1.4.

In order to make the use of the module more resistant against program crashes, it may be desirable to include checks for the index ranges in each operator. This will slow down the execution time only little, but it will be of great help especially in the phase of program development.

In the straightforward way the module is written it may be inefficient to use in certain special applications. As we saw in the last example, there the module could be used more efficiently if we had the possibility to modify the index range of the Taylor coefficients to be computed. This can be achieved in several ways like e.g. introducing global variables in the module which indicate the index range of the coefficients to be computed. Another possibility would be to integrate this information into the data type itaylor, e.g. by using a suitable record or taking additional array components to hold this information. Similarly a result length could be introduced indicating for the resulting Taylor polynomial of each operation

up to which index the series could actually be computed (e.g. if an error occurred in the computation or operands with a differing number of terms were supplied, or if an operation like differentiation, (5.19), should be used also). An additional advantage of such a modification would be that monomials or polynomials with only few coefficients differing from zero could be handled considerably faster. For such an approach see e.g. [88].

In the case of division $u/v$ the operator for itaylor/itaylor breaks down if both Taylor polynomials $u$ in the numerator and $v$ in the denominator start with a constant term equal to zero. However, often we still can compute a correct result by applying de L'Hospitals rule, i.e. by differentiating $u$ and $v$ and taking the quotient $u'/v'$ as operands for the division. If necessary the differentiation has to be performed several times. However, it should be noted that in this case we can no longer compute the same number of Taylor coefficients for $u/v$ as we had in the operands $u$ and $v$. Hence an indication of the actual length of the resulting series should be generated as dicussed in the previous paragraph.

Automatic differentiation for the computation of Taylor coefficients was already used by R.E. Moore in 1965 for the solution of ordinary initial value problems. Later many important contributions came from Rall, Corliss, Griewank, Iri, Fischer and others. A recent collection of research and overview papers as well as an extended bibliography is contained in [115].

## 5.2 Functions in Several Variables, Gradients

### 5.2.1 Introduction

For a one dimensional function the computation of first order derivatives is a trivial special case of the computation of Taylor coefficients as we have done it in the previous Section. For a function in several variables there is in principle no difference also since we have to follow exactly the same pattern and repeat it for each of the independent variables, i.e. we have to implement a Taylor arithmetic which computes the first derivatives with respect to each independent variable and stores it in a vector. This so-called *forward mode* of automatic differentiation for gradients has been discussed in many places already, see [247], [268], [124] and others.

However, in this forward mode the cost for computing a value $f(x)$ and its gradient $\nabla f$ is about $n+1$ times higher than the cost for computing $f(x)$ alone, since each (scalar) operation $f_k$ in $f$ is now replaced by a vector operation involving $f_k$ and $\nabla f_k$.

Approximately the same increase in cost comes also with the computation of finite differences as an approximation for $\nabla f$.

Therefore it is astonishing that a method exists which is able to deliver $\nabla f$ at a cost which is bounded by a *constant* multiple of the cost for computing $f$ alone – i.e. this constant is independent of the number $n$ of independent variables in the vector $x$. The value of this constant is less than 5, see e.g. [114], [104], [148], and

in most cases the computation of $f$ and its gradient $\nabla f$ turns out to be only little more than twice as expensive as the computation of $f$ alone.

This enormous reduction of computational complexity is achieved by a very economic way of the application of the chain rule. However, the price we have to pay for this fast method, the so-called *reverse mode* of automatic differentiation, is that we have to store each intermediate result of the computation of $f$ until the process of determining $\nabla f$ is completed. For complicated functions $f$ with a large number of variables i.e. when $x$ has very high dimension this may be a considerable amount of storage.

### 5.2.2 Theoretical Background

Let $x \in R^n$ be a vector of independent variables and $f(x)$ an expression whose value and whose gradient $\nabla f(x)$ are sought. We decompose $f$ into its individual operations $f_k$ in the following way.

First we identify the $n$ independent variables $x_1, \ldots, x_n$ in $x$ as $f_1, \ldots, f_n$:

$$\begin{aligned} f_1 &= x_1 \\ &\vdots \\ f_n &= x_n \ . \end{aligned} \tag{5.23}$$

Next, we assume that $f$ contains $m$ constants $c_1, \ldots, c_m$, which we call

$$\begin{aligned} f_{n+1} &= c_1 &= x_{n+1} \\ &\vdots \\ f_{n+m} &= c_m &= x_{n+m} \ . \end{aligned} \tag{5.24}$$

The remaining $f_k$'s are now the operations which are actually performed in $f$:

$$\begin{aligned} f_{n+m+1} &= f_{n+m+1}(x_1, \ldots, x_{n+m}) &= x_{n+m+1}(x_1, \ldots, x_{n+m}) \\ &\vdots \\ f = f_N &= f_N(x_1, \ldots, x_{N-1}) &= x_N(x_1, \ldots, x_{N-1}) \ . \end{aligned} \tag{5.25}$$

The values $x_{n+m+1}, \ldots, x_N$ are the intermediate values which are obtained as the expression is computed and the final value, $x_N$ is the value of $f$. All other $f_k$ in (5.25) usually depend only on one or two of the previous $x_k$'s, so the system in (5.23) – (5.25) is extremely sparse. The operations appearing as $f_k$, $k = n+m+1, \ldots, N$ are typically the arithmetic operations $+, -, *, /$ in which case $f_k$ depends only on two variables or they are calls to standard functions like $\sin, \cos, \exp$, etc. in which case $f_k$ even depends on one variable only. This decomposed form (5.23) – (5.25) is sometimes called the *code list* of $f$, see e.g. [114], [104]. Of course the decomposition into such a code list is not unique, in fact even for simple expressions there are usually many possibilities to generate a code list.

Now we associate with each $x_k$ an *adjoint value* $g_k$ which is the derivative of the final value $f = x_N = f_N$ with respect to the variable $x_k$:

$$g_k := \frac{\partial x_N}{\partial x_k}, \quad k = 1, \ldots, N \ . \tag{5.26}$$

Obviously we have

$$g_N = 1 \quad \text{and} \quad \nabla f = (g_1, \ldots, g_n) \; . \tag{5.27}$$

From the chain rule we also get immediately

$$\begin{aligned} g_k &= \frac{\partial x_N}{\partial x_k} = (\frac{\partial f_N}{\partial x_1}, \ldots, \frac{\partial f_N}{\partial x_{N-1}}) \cdot (\frac{\partial x_1}{\partial x_k}, \ldots, \frac{\partial x_{N-1}}{\partial x_k}) \\ &= \frac{\partial f_N}{\partial x_k} + \sum_{i=k+1}^{N-1} \frac{\partial f_N}{\partial x_i} \cdot \frac{\partial x_i}{\partial x_k} \\ &= \sum_{i=k+1}^{N} \frac{\partial f_i}{\partial x_k} \cdot g_i \; . \end{aligned} \tag{5.28}$$

since $x_1, \ldots, x_{k-1}$ do not depend on $x_k$ and $\partial x_k / \partial x_k = 1$.

This is a recursive formula for the adjoint values $g_k$ which can be applied backwards starting from $k = N$ with $g_N = 1$ and then evaluating $g_k$ for $k$ down to 1. Therefore the method is also called the *reverse mode* of automatic differentiation.

The last sum in (5.28) has the following meaning: The $k$-th adjoint value $g_k$ is obtained by accumulating all products $\partial f_i / \partial x_k \cdot g_i$ from those operations $f_i$ in which $x_k$ appears as an operand. If $x_k$ does not appear in $f_i$ then trivially $\partial f_i / \partial x_k = 0$.

We see that the computation of $f$ and $\nabla f$ can be divided into two phases:

**The forward sweep:**
This is the computation of the function value $f$ starting with $x_1$ at the beginning of the code list and ending with the final value $x_N = f_N = f$.

**The reverse sweep:**
This is the computation of the adjoint values $g_k$ starting with $g_N = 1$ at the end of the code list and stepping backwards through the list ending with the final value $g_1$. At the end of this reverse sweep the components of $\nabla f$ can be found in $g_1, \ldots, g_N$.

The partial derivatives $\partial f_i / \partial x_k$ must be calculated for each operation $f_i$. Since for the $f_i$ we use only a relatively small set of operations i.e. the arithmetic operations and the usual standard functions, these partial derivatives can be calulated and programmed once just as in the case of a forward method (see e.g. the Taylor arithmetic in the previous section 5.1). In the following table we summarize these

derivatives for the basic arithmetic operations:

| $f_i$ | $\frac{\partial f_i}{\partial x_k}$ | $f_i$ | $\frac{\partial f_i}{\partial x_k}$ |
|---|---|---|---|
| $x_k + x_r$ | $1$ | $x_k \cdot x_r$ | $x_r$ |
| $x_l + x_k$ | $1$ | $x_l \cdot x_k$ | $x_l$ |
| $x_k - x_r$ | $1$ | $\frac{x_k}{x_r}$ | $\frac{1}{x_r}$ |
| $x_l - x_k$ | $-1$ | $\frac{x_l}{x_k}$ | $\frac{-f_i}{x_k}$ |

(5.29)

Table 4.2: Derivatives for the basic arithmetic operations

Similarly we get the next table for the derivatives $\partial f_i/\partial x_k$ if $f_i$ is a standard function:

| $f_i$ | $\frac{\partial f_i}{\partial x_k}$ | $f_i$ | $\frac{\partial f_i}{\partial x_k}$ | $f_i$ | $\frac{\partial f_i}{\partial x_k}$ |
|---|---|---|---|---|---|
| $x_k^2$ | $2x_k$ | $\sin x_k$ | $\cos x_k$ | $\sinh x_k$ | $\cosh x_k$ |
| $\sqrt{x_k}$ | $\frac{1}{2f_i}$ | $\cos x_k$ | $-\sin x_k$ | $\cosh x_k$ | $\sinh x_k$ |
| $e^{x_k}$ | $f_i$ | $\tan x_k$ | $1 + f_i^2$ | $\tanh x_k$ | $1 - f_i^2$ |
| $2^{x_k}$ | $f_i \ln 2$ | $\cot x_k$ | $-(1 + f_i^2)$ | $\coth x_k$ | $-(1 - f_i^2)$ |
| $10^{x_k}$ | $f_i \ln 10$ | $\arcsin x_k$ | $\frac{1}{\sqrt{1 - x_k^2}}$ | $\operatorname{arsinh} x_k$ | $\frac{1}{\sqrt{x_k^2 + 1}}$ |
| $\ln x_k$ | $\frac{1}{x_k}$ | $\arccos x_k$ | $\frac{-1}{\sqrt{1 - x_k^2}}$ | $\operatorname{arcosh} x_k$ | $\frac{1}{\sqrt{x_k^2 - 1}}$ |
| ${}_2\log x_k$ | $\frac{1}{x_k \ln 2}$ | $\arctan x_k$ | $\frac{1}{1 + x_k^2}$ | $\operatorname{artanh} x_k$ | $\frac{1}{1 - x_k^2}$ |
| ${}_{10}\log x_k$ | $\frac{1}{x_k \ln 10}$ | $\operatorname{arccot} x_k$ | $\frac{-1}{1 + x_k^2}$ | $\operatorname{arcoth} x_k$ | $\frac{1}{1 - x_k^2}$ |

(5.30)

Table 4.3: Derivatives for standard functions

It is obvious how the computation of $f$ using the code list and the forward sweep has to be done. Less obvious is how the reverse sweep should be organized even knowing all the partial derivatives from the tables above. In literature we can find

many different ways to implement the reverse sweep, see e.g. [114], [104] and others. Here, we will discuss a very intuitive way for the realization of the reverse sweep which, in addition, is also very easy to implement in PASCAL-XSC.

Instead of using the code list directly we rather construct an equivalent representation of $f$ in the form of a *computational graph* which is similar to a binary tree. Each node of this graph represents one of the operations $f_i$, i.e. some nodes represent just the independent variables $x_1, \ldots, x_n$ and the constants $c_1 = x_{n+1}, \ldots, c_m = x_{n+m}$. In the node representing $f_i$ we store the corresponding values $x_i$ and $g_i$ as well as the information what operation has to be done in this node and pointers to the operands. We write the final node for $f = f_N = x_N$ at the top and put the others below recursively drawing a line from an upper node to a lower node if the upper one uses the lower one as an operand.

With this representation the forward sweep and the reverse sweep both can be carried out by recursively traversing the graph and thereby computing the desired values. In the forward sweep we compute the values $x_i$ starting from the known values $x_1, \ldots, x_{n+m}$ at the bottom of the graph and going upwards ending with $f = f_N = x_N$ at the top of the graph. In addition, while carrying out the forward sweep we initialize the adjoint values $g_i$ in each node with zero such that in the reverse sweep we can accumulate these quantities without any further initializations. The reverse sweep is carried out in the other direction, starting at the top of the graph with $g_N = 1$ and computing recursively the other $g$-values in the following way: in the node corresponding to $f_i$ compute $\partial f_i / \partial x_k$ for each operand occurring in this node (there are at most two of them) and add the product of this derivative with the $g$-value $g_i$ of the current node to the $g$-value $g_k$ of the operand-node $f_k$

As an example for the computation of $f$ and the adjoint values $g_k$ in a computational graph consider the simple function

$$f(x_1, x_2, x_3) = x_1 x_2 x_3$$

from $\mathbb{R}^3 \to \mathbb{R}$.

We decompose $f$ into the following code list:

$$\begin{array}{rcccccc} & & f_1 & = & x_1 & & \\ & & f_2 & = & x_2 & & \\ & & f_3 & = & x_3 & & \\ & & f_4 & = & x_4 & = & x_2 x_3 \\ f & = & f_5 & = & x_5 & = & x_1 x_4 \end{array}$$

The computational graph corresponding to this code list is shown in the following figure. Also the values of all intermediate results $x_i$ and $g_i$ are denoted there. $f$ and $\nabla f$ are computed for the argument $x = (3, -2, 4)$. Each node $f_i$ is drawn by use of a box containing three lines, the first line indicating the operation corresponding to this node, the second and third line containing the values of $x_i$ and $g_i$ for this node.

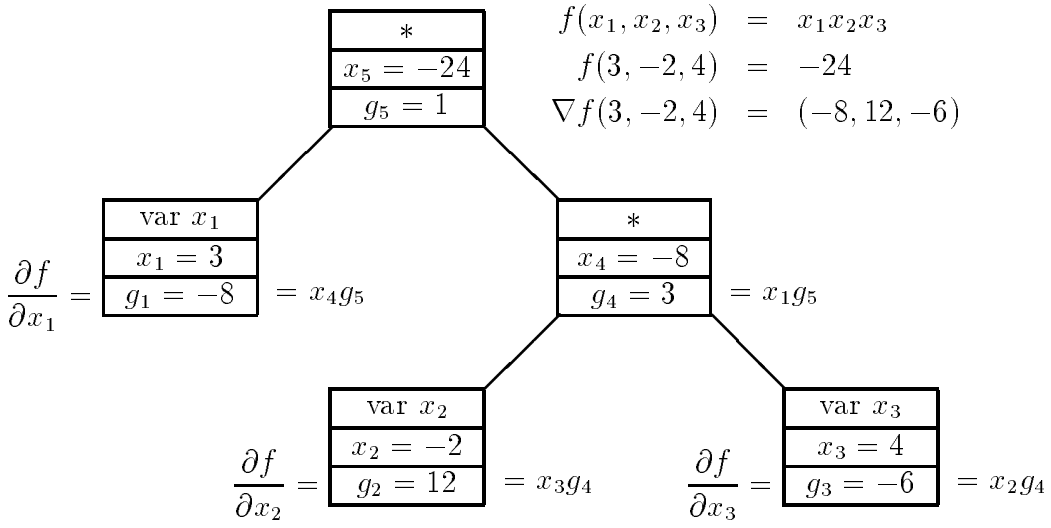

Figure 5.1: any comment ?

### 5.2.3 Algorithms

In this section we discuss the forward and the reverse sweep in a more algorithmic setting from which we will be able to write our PASCAL-XSC module.

We will formulate the forward sweep as a collection of operators and functions each of which implements a basic operation $f_i$. In each such operation a node of the computational tree will be generated and its components will be initialized properly:

- A component `op` contains the operation which has to be performed in this node.
- Two components `l` and `r` are pointers to the two operands (if there is only one operand, then `r` is not used).
- Two components `x` and `g` hold the function value $x_i$ of the current node which is initialized with this value already at node generation and the adjoint value $g_i$ which is initialized with zero at node generation time. The proper adjoint values will be accumulated in `g` later when the reverse sweep is carried out.
- A component `sub` which counts the references to this node from other nodes. I.e. `sub` indicates how often the current node appears as a subexpression in $f$.

Among the algorithms for the forward sweep there is a special one, `newf`, which is dedicated to the generation and initialization of a node for the computational graph. All the other ones call `newf` with suitable parameters to generate their specific node. These algorithms are very simple, in fact they are almost identical with each other differing only in the kind of operation which they perform. Therefore we only list three algorithms: the special algorithm `newf`, one example for a binary operator and another example for a standard function. The complete set of algorithms is listed in the program text in Section 5.2.4.

### Algorithm 5.13: Newf $(op, a, b, x)$ {function}

{Generation of a formula node}
**input:** Operation code $op$, formula pointers $a, b$, interval $x$ (function value of the node)
**output:** Pointer to the node generated (as function value)

(a) new($f$) {allocate new node f}

(b) {initialize node $f$}
$f \uparrow .op := op$
$f \uparrow .l := a$
$f \uparrow .r := b$
$f \uparrow .x := x$
$f \uparrow .g := 0.0$
$f \uparrow .sub := -1$ {subexpression counter}

(c) Newf:= $f$ {return pointer to generated node}

### Algorithm 5.14: $+(a, b)$ {operator}

{Add two formula nodes}
**input:** Formula pointers $a, b$
**output:** Pointer to the node generated (operator result)

(a) {increase reference counter in operands}
$a \uparrow .sub := a \uparrow .sub + 1$
$b \uparrow .sub := b \uparrow .sub + 1$

(b) {do operation}
**return** Newf $(op\_plus, a, b, a \uparrow .x + b \uparrow .x)$

### Algorithm 5.15: Sin $(a)$ {function}

{Sine of a formula node}
**input:** Formula pointer $a$
**output:** Pointer to the node generated (function result)

(a) {increase reference counter in operand}
$a \uparrow .sub := a \uparrow .sub + 1$

(b) {do operation}
Sin :=Newf $(op\_sin, a, NIL, \sin(a \uparrow .x))$

In contrast the reverse sweep consists of just one function, `eval`, which by use of a local procedure traverses the graph recursively and accumulates the adjoint values in all nodes. Depending on the kind of operation in node $f_i$ the product $\partial f_i / \partial x_k \cdot g_i$ is determined in a case-statement and added to $g_k$ of the operand node $f_k$. In the following algorithm we do not list each of the different cases since as in the forward sweep they are all very similar and are listed in detail in the program text. The local procedure `reverse_sweep` is as follows.

## Algorithm 5.16: ReverseSweep $(f)$ {procedure}

{Reverse sweep for a formula f, local procedure to EVAL }
**input:** formula pointer $f$
**output:** none
**side effects:** computes all adjoint values in the graph of $f$, disposes the storage of the graph of f after this computation

(a) {accumulate $\partial f_i/\partial x_k \cdot g_i$ into $g_k$ of the operands}
**case** $f \uparrow .op$ **of**

constant: nothing to do
variable: nothing to do
plus: $f \uparrow .l \uparrow .g := f \uparrow .l \uparrow .g + f \uparrow .g$
$f \uparrow .r \uparrow .g := f \uparrow .r \uparrow .g + f \uparrow .g$
minus: $f \uparrow .l \uparrow .g := f \uparrow .l \uparrow .g + f \uparrow .g$
$f \uparrow .r \uparrow .g := f \uparrow .r \uparrow .g - f \uparrow .g$
mult: $f \uparrow .l \uparrow .g := f \uparrow .l \uparrow .g + f \uparrow .g \cdot f \uparrow .r \uparrow .x$
$f \uparrow .r \uparrow .g := f \uparrow .r \uparrow .g + f \uparrow .g \cdot f \uparrow .l \uparrow .x$
div: $f \uparrow .l \uparrow .g := f \uparrow .l \uparrow .g + f \uparrow .g / f \uparrow .r \uparrow .x$
$f \uparrow .r \uparrow .g := f \uparrow .r \uparrow .g - f \uparrow .g \cdot f \uparrow .x / f \uparrow .r \uparrow .x$
sin: $f \uparrow .l \uparrow .g := f \uparrow .l \uparrow .g + f \uparrow .g \cdot \cos(f \uparrow .l \uparrow .x)$

$\vdots$ similarly for all other standard functions

**end case**

(b) {call ReverseSweep recursively for left operand}
**if** $f \uparrow .l \neq$ NIL **then**
**if** $f \uparrow .l \uparrow .sub \leq 0$ **then** ReverseSweep $(f \uparrow .l)$
**else** $f \uparrow .l \uparrow .sub := f \uparrow .l \uparrow .sub - 1$

(c) {call ReverseSweep recursively for right operand}
**if** $f \uparrow .r \neq$ NIL **then**
**if** $f \uparrow .r \uparrow .sub \leq 0$ **then** ReverseSweep $(f \uparrow .r)$
**else** $f \uparrow .r \uparrow .sub := f \uparrow .r \uparrow .sub - 1$

(d) {node f is no longer needed, if not independent variable then free used memory}
**if** $f \uparrow .op \neq$ variable **then** dispose( $f$ )

The function `eval` contains a local recursive procedure `reverse_sweep` which actually carries out the reverse sweep. `eval` itself does nothing else but returning the value of $f$ which has been computed in the forward sweep, initializing the adjoint value $g_N := 1$ and starting the reverse sweep by a call to the local procedure `reverse_sweep`.

## Algorithm 5.17: Eval $(f)$ {function}

{Evaluation and reverse sweep for a formula $f$ }
**input:** formula pointer $f$

**output:** interval containing the value of $f$ (function result)
**side effects:** computes all adjoint values in the graph of $f$, disposes the storage of the graph of $f$ after this computation

(a) **return** $f \uparrow .x$ {has been computed in forward sweep}

(b) {initiate reverse sweep}
$f \uparrow .g := 1$
ReverseSweep$(f)$ {call local recursive procedure}

### 5.2.4 PASCAL-XSC Program Code

The following PASCAL-XSC module `igradrev` contains an implementation of the reverse mode of automatic differentiation as described in the previous sections.

The data type `formula` is used to build the computational graph representing the formulas to be differentiated and is explained in detail in the comment at the beginning of the program. It is a record containing a component `op` which indicates the operation to be done in the current node. Further components are pointers to the left and right operands (`l`,`r`), the function value `x` and the adjoint value `g` of the current node. The component `sub` has a less obvious meaning: it is used to count the references from outside to the current node. In other words the value of `sub` shows how often the partial formula starting at the current node is used as an operand in different operations i.e. how often it appears as a subexpression in $f$.

This is an important information for the reverse sweep since according to (5.28) the adjoint value `g`$= g_k$ in each node $f_k$ is valid only if *all* products $\partial f_i/\partial x_k \cdot g_i$ from *all* operations $f_i$ using $x_k$ are accumulated in `g`$= g_k$.

The basic philosophy underlying this implementation is as follows. For each expression which has to be evaluated the computational graph is constructed by use of the operators and the data type `formula`, i.e. the user writes the expression for $f$ as an ordinary PASCAL-XSC expression using the data type `formula` which automatically generates the computational graph. Simultaneously with the construction of this graph the value of the expression is computed and each intermediate result is stored in the corresponding node of the graph. This phase of graph construction and computation of the function value is the forward sweep.

The backward sweep which computes all adjoint values in the graph is initiated by a call to function `eval`. When this function is finished with the computation of the adjoint values all nodes of the graph are disposed with the exception of the nodes which represent the independent variables. Therefore, in this implementation a computational graph can only be used *once*. This is sufficient and simple to use in many applications since a user does not need to think about allocating and freeing storage. However, in more complex applications it might rather be desirable to keep the graph for further computations. Then the graph generation and the computation of the function value must be separated into two phases, i.e. first the graph must be constructed, second the function values can be computed (forward sweep) and third the adjoint values can be computed (reverse sweep). In such a setting the second

and third step can be repeated as often as desired without reconstructing the graph each time.

The last function, `eval_grad`, in this module can be used to get an easy access to the function value *and* the gradient of an expression: the first argument is the expression to be evaluated, and the second argument is the vector of the $n$ independent variables. Then a call of `eval_grad` returns a vector of length $n+1$ which contains the function value in the first component and the gradient in the remaining $n$ components.

```
MODULE igradrev;

USE i_ari;

END.
```

Concluding this section we mention as in the case of the itaylor module that we can convert the module by only a few simple changes into a module rgradrev for the computation of gradients using the REAL data type, or to a module cgradrev using the COMPLEX data type or even to a module cigradrev using the CINTERVAL data type ( i.e. complex intervals).

Apart from renaming the module the following changes should be made:

- change the USE-clause; no USE is necessary for REAL, `USE c_ari` is needed for COMPLEX and `USE i_ari,c_ari,ci_ari` are needed for CINTERVAL.

- change all occurences of the data type INTERVAL to REAL, COMPLEX or CINTERVAL as desired. The name of the data type formula needs no change as long as the modified module is used alone. If it is used together with a second one (interval and cinterval, say) then a suitable change of this name should be considered.
- discard the calls to the intrinsic function INTVAL in the cases of REAL and COMPLEX.
- operators with mixed operand types (formula, REAL, INTERVAL, COMPLEX and/or CINTERVAL) may be added or deleted as desired.

There are however versions of PASCAL-XSC where many complex standard functions are not implemented (and also not those for complex intervals). With these versions only the basic arithmetic will work in complex, the standard functions will not.

### 5.2.5 Test Results

In the example which we present here for the use of the module igradrev we write a simple verifying solver for a system of nonlinear equations $f(x) = 0$. The module is used to generate an enclosure for the Jacobian matrix $f'(x)$ i.e. we compute each row $f_i'(x)$ of $f'(x)$ by computing the gradient of $f_i(x)$ with the operators and functions in the module igradrev.

We want to find a root of the nonlinear system of equations

$$f(x) = 0, \quad f : \mathbb{R}^n \to \mathbb{R}^n \tag{5.31}$$

i.e. in our verifying context we want to proof that there exists a solution $x^*$ of (5.31) and compute an enclosure thereof.

Starting from an approximation $\tilde{x}$ we compute iterates with the so called Krawczyk operator $K$

$$\begin{aligned} &[x_{k+1}] := K([x_k]) := x_m - Rf(x_m) + (I - Rf'([x_k]))([x_k] - x_m), \\ &x_m \in [x_k] \text{ e.g. } \; x_m = \mathrm{mid}([x_k]) \end{aligned} \tag{5.32}$$

which is a Newton like iteration. Here $R$ is an approximate inverse for the Jacobian matrix at some point in $[x_k]$. Usually one takes $f'(x_m)$, $x_m$ as in (5.32) and computes an approximate inverse of this matrix.

It can be shown that there exists a solution $x^* \in [x_k]$ if the operator maps $[x_k]$ into itself i.e. if the *existence test*

$$[x_{k+1}] = K([x_k]) \subseteq [x_k] \tag{5.33}$$

holds true, see e.g. . [284], [248].

In order to accelerate convergence in the sense that (5.33) will be satisfied as soon as possible we also introduce an $\epsilon$-*inflation*

$$\mathrm{blow}([u], \epsilon) := (1 + \epsilon)[u] - \epsilon[u]$$

which increases the diameter of $[u]$ by a factor of $2\epsilon$ and leaves its midpoint fixed. If $\mathrm{diam}([u]) = 0$ then we set $\mathrm{blow}([u], \epsilon)$ to some interval with midpoint $u = [u]$ and a sufficiently small diameter, e.g. on a computer we take the interval of the next lower and the next upper floating-point number. A solution lying close to $[u]$ is thus more likely to be contained in $\mathrm{blow}([u], \epsilon)$, see [284].

Thus, the algorithm which is implemented in our small demonstration program is as follows:

$X_1 := \tilde{x}$ (given)
$k := 0$
**repeat**
  $k := k + 1$
  $X_0 := \mathrm{blow}(X_1, \epsilon)$
  $x_m := \mathrm{mid}(X_0)$
  $X_1 := x_m - Rf(x_m) + (I - Rf'(X_0))(X_0 - x_m)$
**until** $X_1 \subset X_0$ **or** $k = k_{max}$

where $\tilde{x}$ is a given approximate solution, $\epsilon$ and $k_{max}$ are suitably chosen constants and $f'(X_0)$ is computed row-wise by automatic differentiation with the function eval_grad in module igradrev. The approximate inverse $R$ is computed with the function `MINV` from the standard PASCAL-XSC module lss_aprx.

As a sample function $f$ we choose a simple two-dimensional system which consists of two circles with two intersection points at $(0.5, \pm\sqrt{3}/2)$:

$$\begin{aligned} x_1^2 + x_2^2 - 1 &= 0 \\ (x_1^2 - 1) + x_2^2 - 1 &= 0 \end{aligned}$$

The program uses the module igradrev, some standard arithmetic modules and the module lss_aprx, which contains a function `MINV` for the computation of an approximate inverse $R \approx A^{-1}$ of a matrix $A$. This module is also a standard module of PASCAL-XSC.

```
PROGRAM ignlss;

### 5.2.6 Notes and References

The module can easily be modified to the use of different data types as has already been discussed at the end of Section 5.2.4.

Another possible modification has also been indicated at the beginning of Section 5.2.4: in many applications it is more desirable to keep the graph in memory after the evaluation of forward and reverse sweep in order to do multiple evaluations of the same expression for different arguments. Then the allocation and deallocation of memory is more in the responsibility of the user of the module who has to take more care about this.

Instead of a computational graph we also could use a linear code list like e.g. a sequence of simple instructions in some programming language or a somehow coded sequence of such instructions stored in an array. Then this code list must be interpreted in the forward and reverse sweep and all relevant data must be stored in another list which may be in main memory and/or on a different storage device. There may be two advantaged to such an approach, first there is no need to use pointers which might sometimes make inefficient use of memory (by varying over wide address ranges) and second a code list does not necessarily need to stay in memory completely for all the time, so its size can be larger than the available main memory. The same holds true also for the generated intermediate values $x_i$ and $g_i$ which may be stored elsewhere in this case. See e.g. Griewank's implementation using a so-called 'tape' for these data.

Yet another possibility is a compiler technical approach where we take the function $f$ as a PASCAL-XSC or FORTAN function, say, and write a program which reads this function and compiles it to another function in the same programming language by adding instructions which compute the desired derivatives. For such an approach see e.g. [209], [39] and others.

In [116] Griewank has presented a technique which may reduce the storage complexity of reverse automatic differentiation logarithmically while increasing the time complexity somewhat. This is achieved by taking repeated 'snapshots' of the complete state of the computation and storing these snapshots only during the forward sweep instead of storing all intermediate values. In the reverse sweep then all missing values can be recomputed by use of the values taken from the snapshots.

Further reduction of space and time complexity of reverse automatic differentiation can be achieved by introducing basic operations on higher levels such as matrix-vector operations or even considering problem solvers as basic operations of a function. See e.g. [301] and [302].

Also generalizations to higher derivatives are possible. There exist reverse methods for the computation of Hessian matrices etc. Similarly special methods for the product of a Hessian times a vector and for similar special cases have been developed, see Griewank and others.

## 5.3 Functions in Several Variables, Fast Directional Derivatives

### 5.3.1 Introduction

In many methods and applications it is often not the gradient $\nabla f$ of a function $f$ itself but rather the scalar product $\nabla f \cdot q$ with a certain fixed vector $q$ which is needed. This occurs e.g. in many optimization methods where directional derivatives are needed.

This special problem is treated in this section. From the previous Section 5.2 we can trivially derive a method to solve this task with a cost that is only a constant times the cost for computing $f$ alone, since we can get the gradient $\nabla f$ for this cost and assuming that the cost for evaluating $f$ increases at least linearly with the dimension $n$ the additional scalar product $\nabla f \cdot q$ does not influence the final cost ratio. However, we saw that computing the gradient with the reverse mode of automatic differentiation may need a lot of memory for all intermediate results.

In this section we present a forward method for the computation of $\nabla f \cdot q$ which does not suffer from this high need for memory and which nevertheless requires also an overhead which is less than a constant multiple of the cost for evaluating $f$.

This forward method is due to H. Fischer, [100], and was extended to standard functions by H.-C. Fischer, [101], [104].

### 5.3.2 Theoretical Background

In the following we will use the abbreviation

$$f_q := \nabla f \cdot q$$

for the scalar product of the gradient of a function $f = f(x_1, \ldots, x_n)$ with the fixed vector $q = (q_1, \ldots, q_n)$. Just as in the case of Taylor coefficients, Section 5.1, we consider the derivative, which is a gradient now, for each basic operation in $f$.

For the trivial cases of a constant $c$ or an independent variable $x_i$ and for the arithmetic operations (with $u, v$ functions of $x$) we see immediately:

$$\begin{array}{lllllll} w & = & c & : & w_q & = & 0 \\ w & = & x_i & : & w_q & = & q_i \\ w & = & u \pm v & : & w_q & = & u_q \pm v_q \\ w & = & u \cdot v & : & w_q & = & u v_q + u_q v \\ w & = & u/v & : & w_q & = & (u_q - w v_q)/v \end{array} \tag{5.34}$$

For an arbitrary differentiable function $w(u)$ we get just as easily

$$\nabla w(u) = w'(u) \cdot \nabla u \quad \text{i.e.} \quad (w(u))_q = w'(u) u_q \; . \tag{5.35}$$

For the standard functions $w$ in PASCAL-XSC these derivatives are listed e.g. in (5.30).

As we see from the previous two equations (5.34), (5.35) we only need to compute two scalar quantities: $f$ and $f_q$ using the above relations recursively. The additional overhead for the computation of $f_q$ is obviously bounded by the number of operations which are needed additionally. From (5.34) we see that for $\pm$ this is the same number for $w_q$ as it is for $w$. For $\cdot$ and $/$ it is three times as much for $w_q$ as it is for $w$. Similarly for standard functions $w(u)$ the number of operations needed to compute $(w(u))_q$ is only a small multiple from the cost of computing $w(u)$, compare e.g. (5.30).

### 5.3.3 Algorithms

As in the case of the Taylor coefficients we implement our forward method for the computation of $f$ and $f_q = \nabla f \cdot q$ as an arithmetic operating on pairs of numbers in this case. Introducing the pairs $W = (w, w_q)$ we can write down very simple operators and functions performing the operations to compute $f$ in the first component and to compute $f_q$ in the second component of the pairs.

For these pairs we use the PASCAL-XSC data type

```
TYPE  igrad_q  = RECORD f,fq : INTERVAL END;
```

The algorithms are so simple and easy to implement that we list only a few examples. The rest can be found in the program listing.

## Algorithm 5.18: $+(u, v)$ {operator}

{Computation of $u + v$ and $\nabla(u + v) \cdot q$}
**input:** *igrad_q* $u$, $v$
**output:** Enclosure of $u + v$ and $\nabla(u + v) \cdot q$ (operator result)

$w.f := u.f + v.f$
$w.fq := u.fq + v.fq$
**return** $w.f, w.fq$

In the multiplication operator as well as in the division operator we make use of an exact scalar product:

### Algorithm 5.19: $\cdot\,(u, v)$ {operator}

{Computation of $u \cdot v$ and $\nabla(u \cdot v) \cdot q$}
**input:** *igrad_q* $u$, $v$
**output:** Enclosure of $u \cdot v$ and $\nabla(u \cdot v) \cdot q$ (operator result)

$w.f := u.f \cdot v.f$
$w.fq := \diamondsuit(u.fq \cdot v.f + u.f \cdot v.fq)$
**return** $w.f, w.fq$

Finally, as an example for the standard functions we list the algorithm for arsinh:

### Algorithm 5.20: Arsinh $(u)$ {function}

{Computation of arsinh($u$) and $\nabla(\text{arsinh}(u)) \cdot q$}
**input:** *igrad_q* $u$
**output:** enclosure of arsinh($u$) and $\nabla(\text{arsinh}(u)) \cdot q$ (function result)

$w.f :=$arsinh$(u.f)$
w.fq:= u.fq / $\sqrt{\text{u.f}^2 + 1}$
Arsinh.f:= $w.f$
Arsinh.fq := $w.fq$

## 5.3.4 PASCAL-XSC Program Code

In addition to the operators and functions discussed in the previous Section 5.3.3 the following module `igq_ari` contains conversion operators and functions for converting constants to type igrad_q (by assignments) and to convert two component of two vectors to type igrad_q where one of the vectors must contain the independent variables $x$ and the other the fixed vector $q$.

Also an additional type igq_vector is introduced in this module which is a vector of component type igrad_q, plus two conversions from rvector and from ivector to igq_vector as a vector of constants (implemented as overloaded assignments) and two conversions from rvector and from ivector to igq_vector as a vector of independent variables (implemented as functions).

```

```

Concluding this section we mention as in the case of the itaylor and the igradrev modules that we can convert the module by only a few simple changes into a module rgq_ari for the computation of gradients times fixed vectors using the REAL data type, or to a module cgq_ari using the COMPLEX data type or even to a module

cigq_ari ! ¡=== SUBINDEX! using the CINTERVAL data type ( i.e. complex intervals).

Apart from renaming the module the following changes should be made:

- change the `USE`-clause; no `USE` is necessary for REAL, `USE c_ari` is needed for COMPLEX and `USE i_ari,c_ari,ci_ari` are needed for CINTERVAL.
- change all occurences of the data type INTERVAL to REAL, COMPLEX or CINTERVAL as desired. The name of the data type igrad_q should be changed to rgrad_q, cgrad_q or cigrad_q for clarity.
- discard the calls to the intrinsic function INTVAL in the cases of REAL and COMPLEX.
- operators with mixed operand types (igrad_q, REAL, INTERVAL, COMPLEX and/or CINTERVAL) may be added or deleted as desired.

There are however versions of PASCAL-XSC where many complex standard functions are not implemented (and also not those for complex intervals). With these versions only the basic arithmetic will work in complex, the standard functions will not.

### 5.3.5 Test Results

As a simple test program for our module igq_ari we compute the function value $f(x)$ and the value of the directional derivative $\nabla f(x) \cdot q$ in two different ways: (i) by use of automatic differentiation as implemented in our module and (ii) directly by computing the gradient by hand and using an explicit expression for $\nabla f(x) \cdot q$.

In the program the following test function $f : \mathbb{R}^n \to \mathbb{R}$ is used:

$$f(x) = \left( \sum_{i=1}^{n} \sin x_i^2 \right)^{\frac{1}{2}}$$

whose gradient is

$$\nabla f(x) = \frac{1}{f(x)} (x_1 \cos x_1^2, \ldots, x_n \cos x_n^2) \ .$$

Thus the derivative in direction of a vector $q \in \mathbb{R}^n$ is

$$\nabla f(x) \cdot q = \frac{1}{f(x)} \sum_{i=1}^{n} q_i x_i \cos x_i^2 \ .$$

A sample output of the program shows that the computation of the directional derivative with the help of our module is just as expensive as the direct computation of $f(x)$ and $\nabla f(x) \cdot q$ using an optimal expression for $\nabla f(x)$. The advantage of automatic differentiation of course is, that we do *only* need the expression for $f$ itself and nothing else. The execution times in this output were measured by use

of the standard PASCAL-XSC timer module and are printed in milliseconds. The computation was carried out on an HP 720/9000.

# Chapter 6

# Interval Arithmetic in Staggered Correction Format

Real intervals are usually realized on a computer in such a way that their bounds are chosen as machine numbers, i.e. as floating-point numbers with a fixed precision. Then interval arithmetic is implemented by use of floating-point operations with directed rounding and with results of the same precision. If the machine has floating-point hardware with directed rounding then this kind of interval arithmetic can run at full hardware speed.

Alternatively, sometimes multiple precision real data types are used, again with fixed or with variable precision, especially if ill conditioned problems have to be solved or if there are very high requirements for accuracy of the results. In this case using fast floating-point hardware is no longer possible on traditional hardware since these multiple precision arithmetic operations are usually simulated in integer arithmetic on the computer.

In this chapter we discuss an approach located between these two extremes and which can take full advantage of floating-point hardware provided *only one additional operation* – the *exact scalar product* with a *long accumulator* – is added to the hardware. We represent an interval as a sum of $n$ floating-point numbers $a_i,\ i = 1, \ldots, n$ (which are stored separately) plus one interval $A$ with floating-point bounds (a so called *staggered correction format*). Then all four basic operations $+, -, *, /$ as well as $\sqrt{\ }$ can be efficiently implemented using sums and scalar products of floating-point numbers which are computed exactly in the long accumulator. Also algorithms for standard functions can easily be implemented on the basis of these arithmetical operations.

Of course, using a long accumulator in PASCAL–XSC is no problem, since there the standard data type *DOTPRECISION* is available for this purpose

## 6.1 Introduction

When implementing an interval arithmetic on a computer it is quite natural (and also the most common implementation), to represent real intervals as *machine intervals*; these are intervals whose bounds are machine numbers, i.e., they are floating-point numbers with a *fixed precision*. Then interval arithmetic can be implemented by use of floating-point operations with directed rounding and with results of the same precision. Thus, interval arithmetic can take full advantage of existing floating-point

hardware if this hardware is able to perform directed roundings. This is also the way interval arithmetic is implemented in PASCAL–XSC.

However, in cases where the accuracy of the results is insufficient or no results can be obtained at all due to poorly conditioned problems, it is desirable to have an interval arithmetic of higher precision. Such an arithmetic can easily be obtained if the underlying floating-point system is replaced by a *multiple precision* real arithmetic

as e.g. in [205]. But then the basic operations are generally no longer available in hardware since multiple precision arithmetic has to be simulated by integer arithmetic on the computer. Therefore, execution times will increase drastically if a program uses such a high precision interval arithmetic.

In PASCAL–XSC we have the possibility to solve this problem in a way which can result in execution times closer to those of pure floating-point hardware but still offering a highly increased precision for critical computations. The reason for this is that we have a reliable floating-point arithmetic (i.e. IEEE arithmetic according to the IEEE standard, [143]) and, in addition, we also have the data type *DOTPRECISION* representing a long accumulator. This allows us to implement a new data type *istaggered* for a multiple precision interval arithmetic. With a long accumulator implemented in hardware this *istaggered* arithmetic will run very efficiently and fast using floating-point hardware resources. Such a hardware implementation of a long accumulator has already been developed and will probably soon be available for a large variety of computers ( [32], [33] ). But even if we simulate the long accumulator in software only, as it is done in PASCAL–XSC at the time being, our approach to higher precision still results in similarly fast codes as in the case of usual high precision arithmetic, which is also simulated in software only.

The high precision data type *istaggered* represents intervals as the sum of $n$ floating-point numbers $a_i$, $i = 1, \ldots, n$ (which are stored separately) plus one interval $A$ with floating-point bounds (a so called *staggered correction format*, see [306]). Then all four basic operations $+, -, *, /$ and also $\sqrt{\ }$ can be efficiently implemented using sums and scalar products of floating-point numbers which can be computed exactly in the long accumulator. Also all commonly used elementary functions can be implemented without difficulties for this data format. For simplicity, however, here we only discuss arithmetic operations and $\sqrt{\ }$ in more detail and sketch only what has to be done for standard functions.

## 6.2 Theoretical Background

Let $S$ be the set of all machine numbers on a computer. By $I\mathbb{R}$ we denote the set of all intervals over $\mathbb{R}$ and by $IS$ we denote the set of all *machine intervals*, i.e., all intervals $X = [\underline{x}, \overline{x}]$ with $\underline{x}, \overline{x} \in S$. In this section, we define an interval in *staggered correction format* (or shorter *staggered format*); additionally, we develop algorithms for the four basic operations as well as the square root for this staggered correction data type.

**Definition 1 (Staggered Correction Format)**
*Let* $x_i \in S, i = 1, \ldots, n,\ n \geq 0$, *be machine numbers and* $X \in IS$ *a machine interval. Then*

$$x = \sum_{i=1}^{n} x_i + X \tag{6.1}$$

*is called an interval in* staggered correction format *of length* $n$. *The set of all intervals in staggered correction format of length* $n$ *is denoted by* $IS_n$.

**Remark:**

1. Sometimes we will refer to $x_i$ as the *i-th component* and to $X$ as the *interval component* of a given staggered interval. Of course, in this definition the representation of an interval in staggered correction format is *not unique* in general. In most cases we even may have staggered representations of different lengths for the same interval $x \in I\mathbb{R}$ as, e.g., any sum of zeros plus an interval $X$ for all $X \in IS$. However, this will not present any difficulties, in fact, all calculations will be carried out by use of the long accumulator which is nothing but a long fixed point register and therefore provides a mean for the unique representation of intermediate results.

2. We explicitly allow $n$ to be zero in Definition 1. Then the sum in (6.1) is an empty sum with value zero. In this case we have $IS_0 = IS$ and the staggered correction representation of an interval in $IS_0$ is unique. Nevertheless, in our implementation we will require $n \geq 1$ since this will make some parts of the implementation shorter.

3. It is desirable that the absolute values are ordered as $|x_1| > \ldots > |x_n| > |X|$ and that the exponents of two successive summands $x_i, x_{i+1}$, differ at least by $l$, where $l$ is the mantissa length. We then say that the mantissas in the staggered correction form do not overlap. In this case the interval $x$ is represented with an optimal precision of about $(n+1)l$ mantissa digits. However, this is not a necessary assumption concerning this format: we could even allow all components $x_i$ as well as $X$ to be of the same order of magnitude such that no precision is gained by storing $x$ as a staggered interval. We still could perform all operations and computations but, of course, we would then face a considerable loss of efficiency. Therefore, the non-overlapping property is very desirable, and the operations on $IS_n$ should be written such that they produce results with this property. Our implementation will achieve this property.

4. One advantage of the staggered format is the fact that we can store a number $x$ with high precision using only a few components. If e.g. $x$ is of the form $x = 1 + \epsilon$ with a machine number $\epsilon$ then $x$ can be stored *exactly* even if $\epsilon$ is very small, $|\epsilon| < 10^{-m}, m$ large, say. In this case we can store the number $x$ with a precision of $m$ digits by using only a staggered length of $n = 1$ i.e., one real and one interval are sufficient to enclose $x$.

The exact results of the arithmetic operations on staggered intervals are defined as usual in interval analysis: if $x$ and $y$ are two staggered intervals, we treat them as elements of $I\!I\!R$ and define the operations as they are defined there:

**Definition 2 (Exact operations on staggered intervals)**
*Let $x$ and $y$ be intervals in a staggered correction format.*
*Then $x \circ y := \{\zeta \mid \zeta = \xi \circ \eta, \xi \in x, \eta \in y\}$, in the case of $\circ \in \{+, -, *, /\}$, if $0 \notin y$ for $\circ = /$ and $\sqrt{x} := \{\zeta \mid \zeta = \sqrt{\xi}, \xi \in x\}$, if $\inf(x) \geq 0$.*

Of course, we cannot expect the arithmetic operations to produce *exact* results on a computer since we still are limited by the machine precision, i.e. , the length of the long accumulator in this case. However, for any operation $z = x \circ y$ or $z = \sqrt{x}$, we must require that the staggered interval $z$ is a superset of the true mathematical result of $x \circ y$, as is also the case for ordinary machine interval arithmetic: $x \circ y \subseteq z$ and $\sqrt{x} \subseteq z$ . Here we do not require the result $z$ to be optimal in the sense that it is the smallest staggered interval of some prescribed length $n$ containing the true mathematical value of $x \circ y$ or $\sqrt{x}$; rather, we are satisfied with a compromise between the tightness of the enclosure $z$ and the ease and efficiency of the implementation.

We desire the operations to accept staggered operands of any (perhaps differing) length and to produce their result in a staggered format whose length can be prescribed independently of that of the operands. This can be achieved conveniently if all operations follow the same pattern as far as possible: first we compute upper and lower bounds for the true result and store them in two long accumulators. Then by use of proper rounding, these accumulators are converted to a staggered interval of the desired length. Division and square root will be the only operations differing from this pattern.

First we comment on the two unary operations $+$ and $-$. If $x$ is a staggered interval of length $n$ and if $n$ is also the prescribed result length of $+x$ and $-x$, then $+$ is the identity where no operation is necessary, and $-$ is the operation reversing the signs of all components of $x$. However, if the prescribed result length is $m \neq n$ then there are two cases. The first case, where $m > n$, is similar to the case of $m = n$: all components of $x$ must be copied (with or without a reversal the signs) and only the additional $m - n$ real components of the result have to be set to zero. The second case, however, where $m < n$ requires the execution of some nontrivial operations; we define two accumulators *lo* and *up* to store the bounds of $x$: $lo := \sum_{i=1}^{n} x_i + \underline{X}$ and $up := \sum_{i=1}^{n} x_i + \overline{X}$. Then these accumulators are converted to a staggered interval of length $m$ by the same procedure which is used to obtain the results for the other operations.

This *conversion* of two accumulators *lo* and *up* to an staggered interval $x$ of length $n$ is now outlined. Let *lo* and *up* be two long accumulators and $n \geq 0$ a prescribed staggered length. Then *lo* and *up* are converted to $x$ by use of the following algorithm Convert. Here, *lo* and *up* are long accumulators, $xl, xu, x_i$ are reals, $X$ is an interval, $i, n$ are integers, and *stop* is a boolean variable. We list algorithm Convert already in a more algorithmic form since it is less mathematical

in nature.

*Conversion of two accumulators lo,up to an istaggered* :
*Input:* accumulators $lo$ and $up$ and result length $n$
*Output:* staggered interval $x$

$$
\begin{array}{l}
stop := false \\
i := 0 \\
repeat \\
\quad i := i + 1 \\
\quad xl := \square lo \\
\quad xu := \square up \\
\quad if\ xl = xu\ then\ x_i := xl \\
\qquad\qquad\qquad\qquad lo := lo - xl \\
\qquad\qquad\qquad\qquad up := up - xu \\
\qquad\qquad\quad else\ x_i := 0 \\
\qquad\qquad\qquad\quad stop := true \\
until\ stop\ or\ i = n \\
for\ i := i + 1\ to\ n\ do\ x_i := 0 \\
X := [\bigtriangledown lo, \bigtriangleup up]
\end{array}
\tag{6.2}
$$

Here, $\square, \bigtriangledown, \bigtriangleup$ represent the roundings of the accumulator to the nearest, next lower and next upper machine number, respectively. This algorithm reads successively real numbers $xl$ and $xu$ from the accumulators and, as long as they are equal and the staggered length has not yet been reached, they are assigned to $x_i$ and subtracted from the accumulators. When $xl$ and $xu$ are different or when the staggered length $n$ for the result $x$ is reached, then the remaining values in the accumulators are converted to the interval component $X$ of $x$ using proper rounding. In the case that some $x_i$'s are not yet defined, they are set to zero. This algorithm has the property that the real components of $x$ do not overlap in the sense described above. Thus, this property will also hold true for the results of the following operators where algorithm Convert is used.

Next, we consider *addition* and *subtraction* of staggered intervals. There we simply add (subtract) the lower and upper bounds of two staggered operands $x$ and $y$ into two accumulators and convert them to the result $z$ using the above algorithm Convert . Here, $lo$ and $up$ are long accumulators, $x_i, y_i$ are reals, $X, Y$ are intervals, and $z$ is the resulting staggered interval.

In the case of addition we have

$$
\begin{array}{lcl}
up & := & \sum\limits_{i=1}^{n_x} x_i + \sum\limits_{i=1}^{n_y} y_i \\
lo & := & up + \underline{X} + \underline{Y} \\
up & := & up + \overline{X} + \overline{Y} \\
z & := & \mathsf{Convert}\ (\ lo,\ up\ )
\end{array}
\tag{6.3}
$$

and analogously in the case of subtraction:

$$\begin{array}{lcl} up & := & \sum\limits_{i=1}^{n_x} x_i \; - \; \sum\limits_{i=1}^{n_y} y_i \\ lo & := & up + \underline{X} - \overline{Y} \\ up & := & up + \overline{X} - \underline{Y} \\ z & := & \mathsf{Convert}\,(\; lo,\; up\;) \end{array} \tag{6.4}$$

Obviously, addition and subtraction are straightforward. *Multiplication* however can be implemented in various ways yielding different results because of the subdistributive law of interval arithmetic. Let $x = \sum_{i=1}^{n_x} x_i + X$ and $y = \sum_{j=1}^{n_y} y_j + Y$ be two staggered intervals then, due to subdistributivity, we have:

$$\begin{array}{rcl} xy & = & (\sum\limits_{i=1}^{n_x} x_i + X) \cdot (\sum\limits_{j=1}^{n_y} y_j + Y) \\ & \subseteq & \sum\limits_{i=1}^{n_x} \sum\limits_{j=1}^{n_y} x_i y_j + X \cdot \sum\limits_{j=1}^{n_y} y_j + Y \cdot \sum\limits_{i=1}^{n_x} x_i + XY \\ & \subseteq & \sum\limits_{i=1}^{n_x} \sum\limits_{j=1}^{n_y} x_i y_j + \sum\limits_{j=1}^{n_y} X y_j + \sum\limits_{i=1}^{n_x} Y x_i + XY. \end{array} \tag{6.5}$$

This seems to suggest that better results can be obtained from using the second line in (6.5) than from using the third line. However, in order to compute the products $X \sum_{j=1}^{n_y} y_j$ and $Y \sum_{i=1}^{n_x} x_i$ we first have to round the sums to machine intervals, $\diamondsuit(\sum_{j=1}^{n_y} y_j)$ and $\diamondsuit(\sum_{i=1}^{n_x} x_i)$. As a consequence of these additional roundings, however, now the second line in (6.5) often yields *coarser* enclosures than the third line.

Therefore, we choose line three in (6.5) as the basis of our multiplication algorithm. Here, again, $lo$ and $up$ are long accumulators, $x_i, y_i$ are reals, $X, Y$ are intervals, and $z$ is the resulting staggered interval.

$$\begin{array}{lcl} lo & := & \sum\limits_{i=1}^{n_x} \sum\limits_{j=1}^{n_y} x_i y_j \\ up & := & lo \\ [lo, up] & := & [lo, up] + \sum\limits_{j=1}^{n_y} X y_j + \sum\limits_{i=1}^{n_x} Y x_i + XY \\ z & := & \mathsf{Convert}\,(\; lo,\; up\;) \end{array} \tag{6.6}$$

Up to now, we were able to compute bounds for the results of our operations in two accumulators and then round these to an interval staggered format. This can no longer be carried out conveniently in the case of the *division* of two staggered correction intervals $x$ and $y$. Rather, we will apply an iterative algorithm computing successively the $n_z$ real components $z_i$ of the quotient $x/y$.

In order to compute this approximation $\sum_{i=1}^{n_z} z_i$, we start with $z_1 = \square m(x)/\square m(y)$; here $m(a)$ represents a point selected in $a$, e.g. the midpoint and $\square$ is the rounding to $S$. Now, we proceed inductively: if we have an approximation $\sum_{i=1}^{k} z_i$, then we can compute a next summand $z_{k+1}$ by use of

$$z_{k+1} = \square \Big( \sum_{i=1}^{n_x} x_i - \sum_{i=1}^{n_y} \sum_{j=1}^{k} y_i z_j \Big) / \square(m(y)), \tag{6.7}$$

where the numerator is computed exactly using a long accumulator and is rounded only once to $S$. The division is performed in ordinary floating-point arithmetic.

As in the previous operations, this iteration guarantees that the $z_i$ do not overlap since the defect (i.e. the numerator in (6.7)) of each approximation $\sum_{i=1}^{k} z_i$ is computed with only one rounding.

Now, the interval component $Z$ of the result $z$ may be computed as follows:

$$Z = \diamondsuit \Big( \sum_{i=1}^{n_x} x_i - \sum_{i=1}^{n_y} \sum_{j=1}^{n_z} y_i z_j + X - \sum_{j=1}^{n_z} z_j Y \Big) / \diamondsuit(y), \tag{6.8}$$

where $\diamondsuit$ is the rounding to an interval in $IS$.

It is not difficult to see that $z = \sum_{i=1}^{n_z} z_i + Z$ as computed from (6.7) and (6.8) is a superset of the exact range $\{\xi/\eta \mid \xi \in x, \eta \in y\}$; in fact, for all $\alpha \in X, \beta \in Y$ we have the identity:

$$\frac{\sum\limits_{i=1}^{n_x} x_i + \alpha}{\sum\limits_{i=1}^{n_y} y_i + \beta} = \sum_{j=1}^{n_z} z_i + \frac{\sum\limits_{i=1}^{n_x} x_i + \alpha - \sum\limits_{i=1}^{n_y} \sum\limits_{j=1}^{n_z} y_i z_j - \sum\limits_{j=1}^{n_z} z_j \beta}{\sum\limits_{i=1}^{n_y} y_i + \beta}.$$

An interval evaluation of this expression for $\alpha \in X$ and $\beta \in Y$ shows immediately that the exact range of $x/y$ is contained in $\sum_{j=1}^{n_z} z_j + Z$, which is computed using (6.7) and (6.8).

Now, it is clear how to get the result $z$ for the division of two *istaggered* variables $x/y$ by the following three computation steps:

1. $z_1 := m(x)/m(y)$
2. compute real parts $z_{k+1}$ from (6.7) for $k = 0, \ldots, n_z - 1$ (6.9)
3. compute interval part Z from (6.8)

An algorithm for the *square root* can be obtained analogously as in the case of the division. We compute iteratively as follows the $z_i, i = 1, \ldots, n_z$ of the approximation part:

$$\begin{aligned} z_1 &= \sqrt{\square(x)} \\ z_{k+1} &= \square \Big( \sum_{i=1}^{n_x} x_i - \sum_{i,j=1}^{k} z_i z_j \Big) / (2 z_1). \end{aligned} \tag{6.10}$$

This guarantees again that the $z_i$ do not overlap since in the numerator of (6.10) the defect of the approximation $\sum_{i=1}^{k} z_i$ is computed with one rounding only. Now, the interval part $Z$ is computed by use of

$$Z = \frac{\diamondsuit \Big( \sum\limits_{i=1}^{n_x} x_i - \sum\limits_{i,j=1}^{n_z} z_i z_j + X \Big)}{\sqrt{\diamondsuit(x)} + \diamondsuit \Big( \sum\limits_{i=1}^{n_z} z_i \Big)}. \tag{6.11}$$

As in the case of the division, it is easy to see that $\sum_{i=1}^{n_z} z_i + Z$ as computed from (6.10) and (6.11) is a superset of the exact range $\{\sqrt{\xi} \mid \xi \in x\}$; in fact, for all $\gamma \in X$ we have the identity:

$$\sqrt{\sum_{i=1}^{n_x} x_i + \gamma} = \sum_{j=1}^{n_z} z_j + \frac{\sum\limits_{i=1}^{n_x} x_i + \gamma - \sum\limits_{i,j=1}^{n_z} z_i z_j}{\sqrt{\sum\limits_{i=1}^{n_x} x_i + \gamma} + \sum\limits_{j=1}^{n_z} z_j}.$$

Now, we see that the square root $z$ of a staggered interval $x$ can be computed by the following three steps very similar to the case if division:

1. $z_1 := \sqrt{\square x}$
2. compute real parts $z_{k+1}$ from (6.10) for $k = 0, \ldots, n_z - 1$ (6.12)
3. compute interval part Z from (6.11)

**Remark:** In the cases of addition, subtraction, and multiplication we have non-overlapping real components $z_i$ since the algorithm Convert is used here. In the cases of division and the square root this property holds true since the defects of the approximations are computed with one rounding only. Nevertheless, it may still be possible that we obtain overlapping in the sense that some $z_i$ will be zero; this may happen e.g. if we choose $n_z$ too large such that underflow occurs when a long accumulator is converted to a staggered interval. It may also happen that we obtain a non-overlapping approximation part $\sum_{i=1}^{n_z} z_i$, which, however, overlaps with the interval part $Z$ in the sense that the absolute value of $Z$ exceeds those of some of the $z_i$'s. This is due to the fact that we allow an arbitrary result length $n_z$ to be specified prior to the computation of the operation such that $n_z$ may be larger than the best possible accuracy of the result (which is limited, of course, by the accuracy of the operands).

## 6.3 Algorithms

For the following algorithms an interval in staggered correction form is assumed to be represented by the following PASCAL–XSC data type:

```
TYPE  istaggered  = DYNAMIC ARRAY [*] OF REAL;
```

The index range of an *istaggered* variable x must always go from $-1$ to n, n $\geq 1$, where the elements with index 1,. . . ,n, are the real components $x_i$ and the elements with index $-1$ resp. 0 are the lower resp. upper bounds of the interval part $X$ of $x$.

Also, in the following algorithms we assume that the actual length $n$ of the *istaggered* variables is contained in a global variable *stagg_prec*. The value of this variable will be used to determine the length of the staggered variables which are the results of the lgorithms.

The staggered length of the operands of the algorithms need not be separate parameters since the upper bounds of the arrays representing the *istaggered* variables can be obtained in PASCAL–XSC by the standard function *ub*( ). Thus for an *istaggered* variable x the staggered length $n_x = ub(\mathrm{x})$.

## Algorithm 6.1: Convert $(lo, up)$ {function}

{Convert two *DOTPRECISIONS* $lo, up$ to an *istaggered*}
**input:** *DOTPRECISIONS* $lo$ and $up$ and result length *stagg_prec*
**output:** *istaggered* containing $[lo,\ up]$ (function's result)

$stop := false$
$i := 0$
**repeat**
  $i := i + 1$
  $xl := \square lo$
  $xu := \square up$
  **if** $xl = xu$ **then** Convert $[i] := xl$
    $lo := lo - xl$
    $up := up - xu$
  **else** Convert $[i] := 0$
    $stop := true$
**until** $stop$ **or** $i = stagg\_prec$
**for** $i := i + 1$ **to** $stagg\_prec$ **do** Convert $[i] := 0$
Convert $[-1] := \bigtriangledown lo$
Convert $[0] := \bigtriangleup up$

Next, we present the algorithms for addition and subtraction according to (6.3) and (6.4). To indicate the use of machine and interval operations we use #-, $\square$- and $\diamond$-signs.

## Algorithm 6.2: $+\,(x, y)$ {operator}

{Add two *istaggereds* $x$ and $y$}
**input:** *istaggereds* $x$ and $y$ of length $n_x$ and $n_y$, respectively
**output:** *istaggered* of length *stagg_prec* containing $x + y$ (operator's result)

$up := \sum_{i=1}^{n_x} x_i + \sum_{i=1}^{n_y} y_i$
$lo := up + \underline{X} + \underline{Y}$
$up := up + \overline{X} + \overline{Y}$
**return** Convert $(\ lo,\ up\ )$

## Algorithm 6.3: $-\,(x, y)$ {operator}

{Subtract two *istaggereds* $x$ and $y$}
**input:** *istaggereds* $x$ and $y$ of length $n_x$ and $n_y$, respectively
**output:** *istaggered* of length *stagg_prec* containing $x - y$ (operator's result)

$up := \sum_{i=1}^{n_x} x_i - \sum_{i=1}^{n_y} y_i$
$lo := up + \underline{X} - \overline{Y}$
$up := up + \overline{X} - \underline{Y}$
**return** Convert $(\ lo,\ up\ )$

The multiplication of two variables in interval staggered format using a computer is performed in a special way for accuracy reasons as described in (6.6).

## Algorithm 6.4: $*\,(x, y)$ {operator}

{Multiply two *istaggereds* $x$ and $y$}
**input:** *istaggereds* $x$ and $y$ of length $n_x$ and $n_y$, respectively
**output:** *istaggered* of length *stagg_prec* containing $x * y$ (operator's result)

$lo := \sum_{i=1}^{n_x} \sum_{j=1}^{n_y} x_i y_j$
$up := lo$
$[lo, up] := [lo, up] + \sum_{j=1}^{n_y} X y_j + \sum_{i=1}^{n_x} Y x_i + X \cdot Y$
**return** Convert ( $lo$, $up$ )

The division of two variables in interval staggered format is carried out by an iteration as introduced in (6.9).

## Algorithm 6.5: $/\,(x, y)$ {operator}

{Divide two *istaggereds* $x$ and $y$}
**input:** *istaggereds* $x$ and $y$ of length $n_x$ and $n_y$, respectively
**output:** *istaggered* $z$ of length *stagg_prec* containing $x/y$ (operator's result)

$n_z := stagg\_prec$
$lo := \sum_{i=1}^{n_x} x_i$
$y_m := \Box m(y)$
$z_1 := (\Box lo)/y_m$
**for** $k := 2$ **to** $n_z$ **do** $lo := lo - \sum_{j=1}^{n_y} y_j z_{k-1}$
$z_k := (\Box lo)/y_m$
$lo := lo - \sum_{j=1}^{n_y} y_j z_{n_z}$
$up := lo$
$Z := \Diamond([lo, up] + X - \sum_{j=1}^{n_z} z_j Y)/\Diamond y$
**return** $Z$

Similar to the division of two variables in interval staggered format the square root is computed in an iterative way (see (6.12)).

## Algorithm 6.6: Sqrt $(x)$ {function}

{Square root of an *istaggered* $x$ }
**input:** *istaggered* $x$ of length $n_x$
**output:** *istaggered* $z$ of length *stagg_prec* containing $\sqrt{x}$ (function's result)

$n_z := stagg\_prec$
$lo := \sum_{i=1}^{n_x} x_i$
$z_1 := \sqrt{\Box(lo)}$

**for** $k := 2$ **to** $n_z$ **do** $lo := lo - 2\sum_{j=1}^{k-2} z_j z_{k-1} - z_{k-1}z_{k-1}$

$z_k := (\Box lo)/(2z_1)$

$lo := lo - 2\sum_{j=1}^{n_z-1} z_j z_{n_z} - z_{n_z}z_{n_z}$

$up := lo$

$Z := \diamondsuit([lo, up] + X)/(\sqrt{\diamondsuit x} + \diamondsuit \sum_{i=1}^{n_z} z_i)$

Sqrt $:= z$

# Applicability of the Algorithms

Since the arithmetic for staggered correction intervals is based on the long accumulator the maximally available precision is also limited by the precision of this long accumulator. If the underlying floating-point format is IEEE double (as is the case in PASCAL–XSC) we have an exponent range of roughly $10^{\pm 308}$ [143]. Thus the available accuracy depends on the order of magnitude of the numbers which are used in the computation. If the numbers' magnitude is $\approx 10^m$ then we can represent it with a precision of at most $308 + m$ decimal digits (using an appropriate length of the staggered representation).

The algorithm for the square root fails in the case when the first approximation $z_1$ of the root is zero. However, this flaw can very easily be avoided by introducing some additional checks on $x$ for zeros before starting the algorithm. The implementation in the next section contains e.g. a simple check for $x$ being exactly zero, before Algorithm 6.6 is started.

In order to make the application of our algorithms easy and efficient, some additional operations from interval arithmetic should be supplied such as the computation of an infimum, supremum, diameter or midpoint. Furthermore, conversion routines from and to other data formats as well as operations with mixed operand types and also some comparison operators are useful for the practical work in a programming language. In the module *istagger* in the next section a collection of such additional routines is embedded such that the module can be used with more benefit.

What is still lacking in the module *istagger* are efficient input/output procedures for staggered intervals. These routines are more difficult to implement. Therefore at the moment the use of staggered variables is confined to the internal computations of a program. The final results, however, do benefit from the higher precision, of course. We also should point out that it does not make much sense to print a staggered variable just component-wise (i.e. for $i := 1$ to $n$ do *write*$(x[i])$). The resulting numbers on the output will be very misleading, since each of the x[i]'s will be rounded individually and independent of the others from the internal binary representation to a decimal representation. Thus each printed component contains a conversion error which makes it impossible to reconstruct the exact value of x.

## 6.4 PASCAL–XSC Program Code

The following PASCAL–XSC module *istagger* contains an implementation of a staggered interval arithmetic using the algorithms described above. The global type *istaggered* representing a staggered correction interval is chosen to be a dynamic array of reals which contains the real values $x_i$ $(i = 1, \ldots, stagg\_prec)$ in the components $1, \ldots, stagg\_prec$ and the lower and upper bound of the interval $X$ in the components $-1$ and 0 resp.

The global variable *stagg_prec*, which is the prescribed result length $n_z$ for all operations, can be altered as desired during the execution of the program. For this purpose the functions *set_precision* and *get_precision* should be used. The functions and operators will then produce results of the new staggered length *stagg_prec* while accepting any length as input. *stagg_prec* must always be positive (zero is not allowed in this module in order to keep the code somewhat simpler). *stagg_prec* is initialized with the value one in the module's main body.

The local function *convert* is the implementation of Algorithm Convert (Algorithm 6.1). The local auxiliary function *add_i_times_ist* is used to add the product of an interval times a point-*istaggered* to two dotprecision variables.

In addition to the algorithms described in the previous sections we have added some functions, procedures and overloaded assignments which make the module more comfortable to use. We do not describe them all here, since each of these routines is very short and contains a comment stating its purpose.

```
MODULE istagger;

USE i_ari,x_real;

## 6.5 Test Results

In this section we will demonstrate a simple but powerful application of staggered interval arithmetic to discrete dynamic systems. Additionally, in the following Section 6.7 we will give some further references to other applications which can be found in the literature.

The computation of orbits of *dynamic systems* is known to be highly unstable if the system exhibits chaotic behavior. In this case, even for the very simplest systems, ordinary floating-point computations will eventually deliver results which are completely wrong quantitatively. Also ordinary interval arithmetic (i.e. intervals of floating-point numbers) will yield poor enclosures after few iterations and, finally, in most cases the computation will break down because of overflow.

By use of the interval staggered correction format, however, we can compute enclosures of orbits for a considerably longer time with high accuracy. Of course this can also be achieved by means of multi-precision arithmetic simulated in software; once the long accumulator is available in hardware, the staggered arithmetic will fully benefit from the speed of floating-point hardware.

Consider the simple dynamic system as given by the *logistic equation*:

$$x_{n+1} = a \cdot x_n \cdot (1 - x_n) \ , \quad n \ \geq \ 0 \tag{6.13}$$

for some $a \in [0, 4]$ and $x_0 \in (0, 1)$.

On the computer, we can compute this iteration with (i) ordinary floating-point arithmetic, (ii) ordinary interval arithmetic or with (iii) staggered interval arithmetic. However, for the cases (ii) and (iii) we will first rewrite the right hand side of (6.13) such that it is better suited for the application of interval arithmetic: For narrow intervals it is well known in interval analysis that a tighter interval enclosure can be obtained by using a *mean value form* instead of an interval evaluation of the originally given expression.

The ordinary interval evaluation of a function $f(x)$ over an interval $X$, denoted as $f(X)$, is obtained via replacing all occurrences of $x$ in $f$ by the interval $X$ and via replacing all operations by the corresponding interval operations. The mean value form is defined by $f_m(X) := f(y) + f'(X)(X - y)$ with some fixed value $y \in X$, e.g., the midpoint. Thus, in the cases (ii) and (iii) we replace the right hand side of (6.13) by its mean value form, i.e. , by

$$\begin{aligned} X_{n+1} &= a \cdot (y_n(1 - y_n) + (1 - 2X_n) \cdot (X_n - y_n)) \\ &\text{with} \quad y_n \ \approx \ \text{mid}(X_n) \ = \ \text{midpoint of } X_n \ . \end{aligned} \tag{6.14}$$

where $X_n$ is an interval in case (ii) and a staggered interval in case (iii). Rewriting (6.13) as (6.14) does not affect the quality of ordinary floating-point computation, which is still executed using (6.13).

The following PASCAL–XSC program uses the module *istagger* from the previous section to compute orbits for this equation. The print-out lists the approximations $x_n$ obtained by ordinary floating-point evaluations of (6.13) and the enclosures $X_n$ as obtained by ordinary and by staggered interval arithmetic using (6.14).

```
PROGRAM ICHAOS;
USE i_ari,istagger; { Import interval and staggered interval arithmetic }

PROCEDURE MAIN;
VAR x,xm : istaggered[-1..stagg_prec];
    y,ym : INTERVAL;
    a,x0 : REAL;
    n,m  : INTEGER;
BEGIN
   WRITELN('Computation of the logistic equation');
   WRITELN('  x(n+1) = a * x(n) * ( 1-x(n) )');
   WRITELN;
   WRITE('enter parameter      a = '); READ(a);
   WRITE('enter initial value x0 = '); READ(x0);
   WRITE('number of iterations m = '); READ(m);
   y:= x0;    { initial value for interval arithmetic           }
   x:= x0;    { initial value for staggered interval arithmetic }
   FOR n:= 1 TO m DO
   BEGIN
      x0:= a*x0*(1-x0);      {  Compute real approximation      }
      {-----------------------------------------------------------}
      { Compute with interval and staggered interval arithmetic }
      { of length stagg_prec. Use mean value form for x(n+1) :  }
      {-----------------------------------------------------------}
      ym:= mid(y);   y := a*( ym*(1-ym) + (1-2*y)*(y-ym) );
      xm:= mid(x);   x := a*( xm*(1-xm) + (1-2*x)*(x-xm) );
      WRITELN(n, ' : ', x0, y, IVAL(x) );
   END;
END;
BEGIN
   WRITE('enter staggered length : '); READ(stagg_prec);
   IF stagg_prec>0 THEN MAIN;
END.
```

For the input data $a = 3.75$, $x_0 = 0.5$ and $n = 500$ iterations we get the following results:

In order to demonstrate the effect of the choice of (6.13) or (6.14), in the following Table 6.2 we list the maximum number $n_{max}$ of iterations which can be performed with staggered interval arithmetic by use of (6.13) or (6.14) and with different choices of the staggered length *stagg_prec*. For larger values of $n$ overflow occurs and the program is aborted (all computations were carried out on the basis of the IEEE double floating-point format).

In all cases here, the accuracy obtained when rounding the results to $S$ is very high (i.e. the maximum accuracy). The accuracy decreases only immediately before reaching $n_{max}$. Pure floating-point computations always yield totally incorrect results after more than about 100 iterations.

## 6.6 Exercises

## 6.7 Notes and References

Elementary functions can be implemented for staggered intervals without difficulties. The algorithms for such implementations may already make use of the staggered operations presented here. As an example, $\exp(x)$ can be implemented by use of the Taylor series which is computed in staggered interval arithmetic, while the remainder term is just an ordinary interval to be added to the interval part of the staggered result. For the inverse functions, it is often very easy to apply an interval Newton's method using staggered interval arithmetic. As an example, $z = \ln x$ can be obtained as the zero of the function $f(z) = x - exp(z)$. Here, only $exp(z)$ and staggered interval arithmetic are needed. A Newton method of this kind can even be implemented quite efficiently making use of the quadratic convergence property: we start the iteration with a small staggered length $n_z$ doubling this length after each iteration step. The overall computational cost will then roughly be only twice as much as the cost for one iteration employing the maximum staggered length that is used.

| *stagg_prec* | $n_{\max}$ with (6.13) | $n_{\max}$ with (6.14) |

Table 6.2: max. iteration count with staggered arithmetic

A different approach to compute results in a staggered correction format avoids a separate implementation of each basic arithmetic operation; rather, the algorithm is rearranged such that it produces its result already in a staggered correction format. Algorithms for linear problems can often be easily transformed in such a way (see e.g. [285]). In fact many of the algorithms in this book compute their results in a format which resembles more or less a staggered correction interval form, see e.g. the algorithms in Chapter 2 and Chapter 3.

The staggered correction format was introduced by Rump, [280], [285], and Böhm, [60], [61], such that elementary operations are not used explicitly. Stetter and Auzinger, [306], [27], proposed the use of this format in a more general, operation-wise way and also coined its name. Klotz, [180], discussed several matrix factorizations using staggered correction arithmetic; since then, staggered correction methods have also been applied to other problems; e.g. the evaluation of multivariate polynomials, [230], the computation of all eigenvalues of symmetric matrices, [231], and the computation of the matrix exponential function, [45], [46].

As a last application we mention *ordinary initial value problems*. The algorithm from [229] which computes guaranteed continuous bounds for the solutions of nonlinear initial value problems, gives its results in the form $x(t) \in \tilde{x}(t) + R(t)$ where $\tilde{x}(t)$ is an approximation of the solution and $R(t)$ is an interval enclosing the global error. Here, it is possible to apply staggered arithmetic in the computation of $\tilde{x}(t)$, however to retain ordinary interval arithmetic in the computation of $R(t)$, which is the most expensive part of the algorithm. Thus, the accuracy of the results can be increased, mainly by increasing the accuracy of the approximation. The increase of the cost for the computation of the global error $R(t)$ is almost negligible.

# Chapter 7

# Multiple-Precision Arithmetic Using Integer Operations

Modules for multiple-precision real [201] and interval arithmetic [200, 203] have been developed in PASCAL-XSC. These modules provide a lot of predefined operations and standard functions for the multiple-precision data types. Due to the concept of overloading of functions and the operator concept of PASCAL-XSC a mathematical notation of expressions also for the multiple-precision data types is possible, which makes the modules applicable in an easy and natural way. Programs become clear and readable.

Both modules described here are under further developement.

In the runtime library of PASCAL-XSC [81], a multiple-precision arithmetic is available [83]. The base used for the representation of mantissa digits is $B = 2^{32}$, i.e., each mantissa digit occupies 32 bits and is implemented by an unsigned 32-bit integer value. Additionaly there are an exponent field as well as some other flags which, for example, indicate that a multiple-precision value is (a) zero, (b) negative, (c) temporary, or (d) exact. The number of mantissa digits that may be used to represent one multiple-precision value is $l_{\max} := 2^{32} - 1$. Such a multiple-precision number needs about $2^{32} \cdot 4 \approx 17 \cdot 10^9$ bytes of storage for its representation. Thus on many machines a further limitation will come from the restricted capacity of the memory of the employed machine. A positive multiple-precision number $x \neq 0$ can be written in the form

$$x = \sum_{n=0}^{l_{\max}-1} m_n B^{ex-n} \ , \quad m_0 \neq 0,\ m_n \in \{0, 1, \ldots, 2^{32} - 1\} \tag{7.1}$$

The exponent $ex$ ranges from $e_{\min} := -2^{31}$ to $e_{\max} := 2^{31} - 1$. For example, the multiple-precision number $0.1_B$ is equal to $1 \cdot B^{-1} = 1/2^{32} = 0.000\ldots01_2 = 2.3283064\ldots_{10} \cdot 10^{-10}$. Equivalently $0.11|2531|93_B \cdot B^2 = 11 \cdot B^1 + 2531 \cdot B^0 + 93 \cdot B^{-1} = 11 \cdot 2^{32} + 2531 + 93 \cdot 2^{-32}$. Here we separate individual mantissa digits of the multiple-precision number by the symbol |.

The required number of mantissa digits (with respect to base $2^{32}$) of a resulting value may be set separately for each operation. All operations consider their arguments to full-length independently from the required length of the result mantissa.

There are numerous elementary mathematical functions such as log, exp, sin, cos, arcsin, ... for arguments of the multiple-precision data type. The values of these functions are guaranteed to be accurate to at least two units in the last mantissa digit of the results. Again the number of required mantissa digits may be chosen

arbitrarily.

The PASCAL-XSC module for real multi-precision computations is named `mp_ari`. The multiple-precision data type is called `mpreal`. The standard procedure to set the precision is `setprec(n)`. The integer value n specifies the number of required mantissa digits of the results of all subsequent operations. The integer standard function `getprec` returns the current precision of the multiple-precision arithmetic. Function `getprec` has no arguments. The default precision setting for the arithmetical operations is 3. This means that the result of a multi-precision operation is chopped after 3 mantissa digits. The default setting especially guarantees, that each IEEE double number (53 mantissa bits) can be converted without conversion error into a multi-precision number.

The module for multi-precision interval arithmetic is called `mpi_ari`. The multi-precision interval data type is named `mpinterval`. The precision setting is achieved using the same procedure `setprec(n)` already mentioned. The result of an elementary mathematical function for this data type is a multiple-precision interval. The resulting interval is a superset of the range of the function over the input interval. The bounds are accurate to at least one unit in the last place with respect to the actual precision setting. Again the precision setting may be changed at any point of the program.

The multiple-precision operations $+$, $-$, $*$, / as well as the elementary mathematical functions are called in the usual way. Here, the operator concept of PASCAL-XSC and the concept of overloading of function names is extensively used. This leads to clear and concise programs which are easy to read and debug.

## 7.1 Multi-Precision Real Arithmetic

We list the entries of the PASCAL-XSC module `mp_ari` for the multi-precision real arithmetic. It includes the definition of the new global data type `mpreal` for real multi-precision numbers.

The following lines of code are extracted from the PASCAL-XSC source `mp_ari.p`. The simple PASCAL-XSC program which performs this task uses operators for strings and is as follows:

```
PROGRAM GlobOut;
{------------------------------------------------------------------------}
{ Purpose: List global functions, operators, and and procedures of       }
{          a PSCAL-XSC module.                                           }
{------------------------------------------------------------------------}
VAR
  InFile  : text;
  FileName: string;
  row     : string;
  NumberOfRows: integer;
BEGIN
  Filename:= 'mp_ari.p';
  writeln('File to be processed: ' + FileName);
  reset(InFile, FileName);
  NumberOfRows:= 0;
  WHILE NOT eof(InFile) DO BEGIN
```

```
    NumberOfRows:= NumberOfRows+1;
    readln(InFile, row);
    IF ('global' IN row) OR ('{=' IN row) THEN writeln(row);
  END;
  writeln('Number of rows processed: ', NumberOfRows);
END.
{-------------------------------------------------------------------------}
```

Only lines beginning with `global` or beginning with `{=` are listed. For the complete source code of the real multi-precision module see the file `mp_ari.p`.

{==========   Module Initalization Part   ====================================}
{=============================================================================}
{====================  Last line of module mp_ari: 1163  ====================}
Number OF rows processed: 1163
```

As may be seen by the preceding listing a large variety of common operators and elementary mathematical functions are realized in this module for multi-precision computations. The frequently used standard function `expo(mp)` gives the exponent of `mp` with respect to base 2 and `mant(mp)` gives the corresponding mantissa of its mpreal argument `mp` normalized to $0.5 \leq$ `mant(mp)` $< 1.0$. For the composition function `comp` it holds `comp(mant(mp), expo(mp))` = `mp`.

## 7.2 Multi-Precision Interval Arithmetic

We now list the entries of the PASCAL-XSC module `mpi_ari` for the multi-precision real interval arithmetic. It includes the definition of the new global data type `mpinterval` for multi-precision intervals. Again only lines beginning with `global` or beginning with `{=` are printed. For the complete source code for the multi-precision interval module see the file `mpi_ari.p`.

```

As may be seen by the preceding listing a large variety of common operators and elementary mathematical functions are realized in this module for multi-precision interval computations.

## 7.3 How to Use the Multi-Precision Modules

This section describes primarily the allocation and freeing of memory for multi-precision data (see [126]).

The basic data type `mpreal` is dynamically realized as a pointer type. The same is true for the components `inf` and `sup` of the multi-precision interval data type `mpinterval`:

```
global mpinterval = global record inf, sup: mpreal end;
```

In both cases it is in the programmer's responsibility to allocate and free memory used for multi-precision data. The modules `mp_ari` and `mpi_ari` provide the following procedures for memory management:

`mpinit`: to allocate variables of type `mpreal` or `mpinterval` depending on the actual precision setting,

`mpfree`: to free the multiprecision variables,

`mpvlcp`: to generate a temporay copy of function, procedure or operator parameters (`mpvlcp` is an abbreviation for multi-precision value copy) and

`mptemp`: to mark a multi-precision variable to be temporarily used, that is it will be freed after it is used for the next time.

These procedures can not be used to allocate and free the result variable of a function or operator definition. This is due to a restriction of standard Pascal. Allocating or freeing of result variables using the procedures above would result in a syntax error at compile time. To solve this problem, the modules make use of a programming trick. Since PASCAL-XSC allows overloading of the assignment operator, one can define a special assignment for arguments of type `mpreal` or `mpinterval`, which itself calls the routines listed above. For this purpose, both modules provide an assignment operator with the following right-hand side:

InitFunc, InitOp: to allocate the result variable, and

TempFunc, TempOp: to mark the result variable to be temporary (that is the variable will be freed when it will have been used for the next time).

Equipped with the utilities just described, we can give five basic rules for implementing programs using the multi-precision arithmetics provided by the modules `mp_ari` and `mpi_ari`.

R1: **Variables** of type `mpreal` or `mpinterval` must be initialized by a call of `mpinit` and should be freed by a call of `mpfree`:

```
VAR
  x: mpreal;
  y: mpinterval;
BEGIN
  mpinit(x); mpinit(y);
  ...
  mpfree(x); mpfree(y);
END;
```

R2: **Value parameters** of type `mpreal` or `mpinterval` must be saved by a call of `mpvlcp` and must be restored by a call of `mpfree`:

```
PROCEDURE DoSomething(x: mpreal);
BEGIN
  mpvlcp(x);
  ...
  mpfree(x);
END;
```

R3: **Reference parameters** must neither be initialized by `mpinit` nor be freed by `mpfree`.

R4: The **result variable of a function** of type `mpreal` or `mpinterval` must be initialized by an assignment of the value `InitFunc` and should be freed by an assignment of the value `TempFunc`:

```
FUNCTION ComputeSomething(...): mpreal;
BEGIN
  ComputeSomething:= InitFunc;
  ...
  ComputeSomething:= TempFunc;
END;
```

R5: The **result variable of an operator** of type `mpreal` or `mpinterval` must be initialized by an assignment of the value `InitOp` and should be freed by an assignment of the value `TempOp`:

```
OPERATOR + (...) add: mpreal;
BEGIN
  add:= InitOp;
  ...
  add:= TempOp;
END;
```

We now proceed with a variety of examples.

## 7.4 Examples

In the following subsections we demonstrate the power of the multiple-precision modules `mp_ari` and `mpi_ari`.

### 7.4.1 Logistic Equation

The first example reconsiders the dynamic system already discussed in Paragraph 6.5. A program similar to the program `ICHAOS` is given. The staggered operations are replaced by multi-precision operations as they are implemented in the modules `mp_ari` and `mpi_ari`. In contrast to staggerd operations the precision now is no longer limited by the exponent range of the underlying floating-point system.

The formula realized by the program `CHAOS` is the mean value form (6.14)

$$\begin{aligned} X_{n+1} &= a \cdot (y_n(1 - X_n) + (1 - 2X_n) \cdot (X_n - y_n)) \\ &\text{with} \quad y_n \approx \text{mid}(X_n) = \text{midpoint of } X_n \ . \end{aligned} \tag{7.2}$$

of the logistic equation (6.13)

$$x_{n+1} = a \cdot x_n \cdot (1 - x_n) \ , \quad n \geq 0 \tag{7.3}$$

The program performs a multi-precision interval iteration to compute an orbit of the logistic equation with parameter $a = 3.75$, starting point $x_0 = 0.5$. We compute 500 iterations using a precision setting of 10.

```
PROGRAM MPICHAOS;  { Logistic Equation Using Multi-Precision Comp. }
USE i_ari,   { Interval operations                 }
    mpi_ari; { Multi-precision interval arithmetic }

VAR nn   : integer;    { Precision setting }
    x, xm: mpinterval;
    z    : INTERVAL;
    a, x0: REAL;
    n, m : INTEGER;
BEGIN
   writeln;
   WRITELN('Computation of the logistic equation');
   WRITELN('  x(n+1) = a * x(n) * ( 1-x(n) )');
   WRITELN;
   WRITE('Precision setting (e.g. 10): '); READ(nn);
   setprec(nn);
   mpinit(x); mpinit(xm);           { Initialize multi-prec. variables }
   WRITE('Parameter a (e.g. 3.75): '); READ(a);
   WRITE('Initial value x0 (e.g. 0.5): '); READ(x0);
   WRITE('Number of iterations m (e.g. 500): '); READ(m);
   WRITELN('        Flp. result                        Enclosure');
   x:= x0;              { Initial value for multi-precision iteration }
   FOR n:= 1 TO m DO BEGIN
     x0:= a*x0*(1-x0);                    { Compute real approximation }
     xm:= mid(x);
     x := a*( xm*(1-xm) + (1-2*x)*(x-xm) );    { Multi-prec. enclosure }
     { The line above realizes the mean value form of the logistic eq. }
     z:=x;
     WRITELN(n:4, ': ', x0:14, ' ', z);
   END;
   mpfree(x); mpfree(xm);           { Deallocate multi-prec. variables }
END.
```

The printout shows an enclosure of $x_{500}$. Please compare the result with the enclosure given in the last line of Table 6.1.

```
Computation of the logistic equation
  x(n+1) = a * x(n) * ( 1-x(n) )

Precision setting (e.g. 10):          10
Parameter a (e.g. 3.75):            3.75
Initial value x0 (e.g. 0.5):         0.5
Number of iterations m (e.g. 500):   500

        Flp. result                        Enclosure
   1:  9.375000E-001 [  9.375000000000000E-001,  9.375000000000000E-001 ]
   2:  2.197266E-001 [  2.197265625000000E-001,  2.197265625000001E-001 ]
   3:  6.429255E-001 [  6.429255008697509E-001,  6.429255008697511E-001 ]
         ...                      ...                      ...
 498:  8.177940E-001 [  5.687786680004961E-001,  5.687786680004963E-001 ]
 499:  5.587763E-001 [  9.197606056052906E-001,  9.197606056052908E-001 ]
 500:  9.245451E-001 [  2.767538774320484E-001,  2.767538774320486E-001 ]
```

A simple modification of the program can be used to find the maximum number $n_{\max}$ of iterations which can be performed with multi-precision interval arithmetic with a specific precision setting. The following table is similar to Table 6.2. The entries in the first column show the precision setting in use. In the second column the corresponding values $n_{\max}$ are listed. The values are given for the mean value form (7.2).

| *setprec* | $n_{\max}$ with (6.14) |
|---|---|
| 10 | 601 |
| 20 | 1176 |
| 30 | 1754 |
| 50 | 3017 |
| 100 | 6185 |
| 150 | 9243 |
| 200 | 12277 |

Table 7.1: max. iteration count with multiple-precision arithmetic

Because the orbit of the dynamical system is a subset of the interval $[0, 1]$ we stop the iteration if the enclosure of $x_n$ is no longer a subset of $[0, 1]$.

### 7.4.2 Multiple-Precision Horner Scheme

We now consider Horner's scheme for the evaluation of the value of a polynomial. We will implement a method to compute the value of a polynomial with at least one ulp accuracy (with respect to the IEEE double data format). We assume that the polynomial coefficients as well as the argument are exactly representable as multi-precision quantities.

Usually, the evaluation of a polynomial $p(x)$ is performed by means of Horner's scheme:

$$p(x) = \sum_{k=0}^{n} a_k x^k = (\cdots((a_n x + a_{n-1})x + a_{n-2})x + \cdots + a_1)x + a_0 \tag{7.4}$$

To get sharp bounds for $p(x)$ we will implement a multi-precision interval version. The precision setting local to the implemented function will be automatically increased until an accuracy corresponding to 53 mantissa bits is reached. The multi-precision enclosure is rounded to the smallest floating-point interval $u$ containing this enclosure. Then we check whether `succ(inf(`$u$`)) >= sup(`$u$`)`. If this requirement is not satisfied, the precision setting of the multi-precision arithmetic will be increased and a better enclosure will be computed by a repetition of Horner's scheme. If this enclosure does not lead to a floating-point interval $u$ satisfying the inequality from above, the precision setting will be increased once more. This process will be repeated until the bounds of the corresponding ordinary floating-point interval are equal or two adjacent floating-point numbers.

**Some Experiments with Fibonacci-Polynomials**

To test our routine we will use a so called Fibonacci polynomial. Let $f_n$ denote the $n$-th Fibonacci number, that is

$$f_0 := 0, \quad f_1 := 1, \tag{7.5}$$

$$f_n := f_{n-1} + f_{n-2}, \quad n \geq 2 \tag{7.6}$$

The first numbers are $0, 1, 1, 2, 3, 5, 8, \ldots$. By induction it can be shown that for any two adjacent Fibonacci numbers $f_n$, $f_{n+1}$ the relation

$$-f_n^6 - 3f_{n+1}f_n^5 + 5f_{n+1}^3 f_n^3 - 3f_{n+1}^5 f_n + f_{n+1}^6 \in \{-1, +1\} \tag{7.7}$$

holds. The value of the expression is $+1$ if $n$ is even and $-1$ if $n$ is odd.

We now define the Fibonacci polynomial $p_n(x)$ in the following way:

$$p_n(x) := -x^6 - 3f_{n+1}x^5 + 5f_{n+1}^3 x^3 - 3f_{n+1}^5 x + f_{n+1}^6 \tag{7.8}$$

Then relation (7.7) shows that

$$p_n(f_n) = \begin{cases} +1 & \text{if } n \text{ is even} \\ -1 & \text{if } n \text{ is odd} \end{cases} \tag{7.9}$$

The polynomial $p_n(x) = \sum_{m=0}^{6} a_m x^m$ is a polynomial of degree 6. Its coefficients are given by $a_0 := f_{n+1}^6$, $a_1 := -3f_{n+1}^5$, $a_2 := 0$, $a_3 := 5f_{n+1}^3$, $a_4 := 0$, $a_5 := -3f_{n+1}$, $a_6 := -1$ .

We will now test our polynomial evaluator using Fibonacci polynomials as input data. In order to handle a point problem we must be sure that the coefficients are computed exactly. This requires an exact computation of the Fibonacci numbers and their respective powers. This is done using the routine `Fibonacci` and the power operator `**` implemented in the module `hornermp`. When creating the polynomial coefficients, the precision setting is increased until all coefficients are representable as multiprecision point intervals. We first list the main program.

```
{------------------------------------------------------------------------}
PROGRAM HornFib;
USE i_ari;     { Real interval arithmetic      }
USE hornermp;  { Multi-precision Horner scheme }
VAR
  k        : integer;           { Loop variable                  }
  n        : integer;           { n-th Fibonacci number is used  }
                                { as argument of the polynomial  }
  fibo_n   : mpinterval;        { n-th Fibonacci number          }
  fibo_np1 : mpinterval;        { n plus first Fibonacci number  }
  res      : interval;          { Enclosure of pol(fibo_n)       }
  fn, fnp1 : interval;          { Auxiliary variables            }
  pol      : polynom[0..6];     { Polynomial of degree 6         }
  thin     : boolean;           { Indicates whether pol is thin  }

{------------------------------------------------------------------------}
BEGIN
  { Initialization of multi-precision quantities }
  mpinit(fibo_n); mpinit(fibo_np1);
  FOR k:= Lb(pol) TO Ub(pol) DO mpinit( pol[k] );
  { Infinite loop, quit by pressing <Control> <C> }
  REPEAT
    writeln;
    write('The n-th Fibonacci number will be used as argument; n=? ' );
    read(n); writeln;
    setprec(2);
    { Generate polynomial coefficients as exactly representable  }
    { multi-precision numbers (point intervals)                  }
    REPEAT
      setprec(getprec+1);   { Increase precision of mp arithmetic }
      fibo_n  := fibonacci(n);
      fibo_np1:= fibonacci(n+1);
      pol[6]:= -1;
      pol[5]:= -3*fibo_np1;
      pol[4]:=  0;
      pol[3]:=  5*(fibo_np1**3);
      pol[2]:=  0;
      pol[1]:= -3*(fibo_np1**5);
      pol[0]:=  fibo_np1**6;
      thin:= true;   { Check whether all coefficients of pol are thin }
      FOR k:= 0 TO 6 DO BEGIN
        thin:= thin  AND  ( diam(pol[k]) = 0.0 );
      END;
    UNTIL thin;
    { Now the polynomial coefficients are point mp-intervals }
    writeln('Required precision to get point coefficients: ', getprec:0);
    res:= Horner( pol, fibo_n );
    writeln('Enclosure of pol(...):     ', res);
    { Check whether the Fibonacci numbers are representable as    }
    {    IEEE double numbers; if so, print them in a short format }
    writeln('Fibonacci numbers used: ');
    fn  := fibo_n;
    fnp1:= fibo_np1;
    IF diam(fnp1) +> diam(fn) = 0 THEN BEGIN
      writeln('  fibo(',n:3,  '): ', inf(fn):0:1);
      writeln('  fibo(',n+1:3,'): ', inf(fnp1):0:1);
    END
    ELSE BEGIN
      writeln('fibo(n):   ', fibonacci(n));
      writeln('fibo(n+1): ', fibonacci(n+1));
    END;
  UNTIL false; { Break by pressing <Control> <C> }
END.
{------------------------------------------------------------------------}
```

Please notice, that each element of the coefficient array representing the polynomial has to be initialized separately. The data type `polynomial` is defined as a global dynamic type in the module `hornermp`. We now list this module:

```
{-------------------------------------------------------------------------}
MODULE hornermp;

USE GLOBAL
  i_ari,   { Real interval arithmetic                    }
  mp_ari,  { Multi-precision real module                 }
  mpi_ari; { Multi-precision interval module             }

{ New global data type for polynomials with multi-precision }
{   coefficients.                                          }
GLOBAL TYPE polynom = GLOBAL DYNAMIC ARRAY[*] OF mpinterval;

{-------------------------------------------------------------------------}
GLOBAL FUNCTION Horner(VAR pol: polynom; VAR pnt: mpinterval): interval;
VAR i, degree, prec, OldPrec, NewPrec: integer;

END;
{-------------------------------------------------------------------------}
BEGIN
  { Nothing to initialize }
END.
{-------------------------------------------------------------------------}
```

All functions and operators implemented in this module handle multiprecision intervals. In general, the precision setting for the computations is determined by the main program. Only the global function `Horner` manipulates the precision setting for intermediate results by itself. The active precision setting when entering this function is restored before leaving the function. In the body of the function the setting is increased until the enclosure of the correct result is not wider than two units in the last place with respect to the IEEE double format. To check the width of the result, the intermediate multiprecision interval is converted to an ordinary floating point interval. For this interval the accuracy requirement is checked. If the exponent of the multiprecision interval is too large or too small the conversion raises an appropriate error message.

In general, the call of `Horner` will result in an infinite loop if the coefficients of the polynomial are no point intervals. This requirement is not checked when entering this routine. In our application, we force (in the main program, when generating these quantities) the diameters of all coefficients as well as the diameter of the argument to be zero.

A sample output of the program is as follows:

```
The n-th Fibonacci number will be used as argument; n=?   20
Required precision to get point coefficients: 3
Precision setting in function Horner: 3
  Intermediate result res: [ 1.000000000000000E+000, 1.000000000000000E+000 ]
Enclosure of pol(...):     [ 1.000000000000000E+000, 1.000000000000000E+000 ]
Fibonacci numbers used:
  fibo( 20): 6765.0
  fibo( 21): 10946.0

The n-th Fibonacci number will be used as argument; n=?    75
Required precision to get point coefficients: 10
Precision setting in function Horner: 3
  Intermediate result res: [              -2.2E+072,               1.2E+073 ]

  Intermediate result res: [              -4.3E+009,               0.0E+000 ]
Precision setting in function Horner: 10
  Intermediate result res: [-1.000000000000000E+000,-1.000000000000000E+000 ]
Enclosure of pol(...):     [-1.000000000000000E+000,-1.000000000000000E+000 ]
Fibonacci numbers used:
  fibo( 75): 2111485077978050.0
  fibo( 76): 3416454622906707.0
```

For the second example (the 75-th Fibonacci number is incorporated) the precision setting local to the function `Horner` is increased 7 times. A final precision setting according to 10 mantissa digits (with respect to base $2^{32}$) gives the point interval $[-1,-1]$ as enclosure of the correct polynomial value $-1$.

### 7.4.3 Arithmetic-Geometric Mean Iteration

In the next section 7.4.4, the computation of $\pi$ to high accuracy will be described. As we will see, the computations may be carried out using the so called arithmetic-geometric mean ($AGM$) iteration. Let $g_0$ and $a_0$ be two positive numbers with $0 < g_0 < a_0$. The geometric mean of these numbers is $g_1 := \sqrt{g_0 a_0}$ while their arithmetic mean is $a_1 := \dfrac{g_0 + a_0}{2}$. In general $g_j$ is defined by $g_j := \sqrt{g_{j-1} a_{j-1}}$ and $a_j$ by $a_j := \dfrac{g_{j-1} + a_{j-1}}{2}$, $j = 1, 2, \ldots$. There holds the following monotonicity property

$$g_0 < g_1 < g_2 < \cdots < g_j < \cdots < a_j < \cdots < a_3 < a_2 < a_1 < a_0. \tag{7.10}$$

The sequences $\{g_j\}$ and $\{a_j\}$ converge to their common limit

$$\lim_{j\to\infty} g_j = \lim_{j\to\infty} a_j = AGM(g_0, a_0). \tag{7.11}$$

The rate of convergence is two.

The $AGM$ method is *not* a self-correcting method like the Newton iteration. All iteration steps have to be performed with a full length arithmetic. The following program is a straightforward implementation in order to get verified bounds for the arithmetic-geometric mean of two positive real numbers. Multiple-precision interval arithmetic is used.

```
PROGRAM AGM;                    { Arithmetic-Geometric Mean Evaluation }

USE mp_ari, mpi_ari;       { Multi-precision real and interval module }

FUNCTION AGM(x, y: mpinterval): mpinterval;
VAR
  a, b, bnew: mpinterval;
BEGIN
  mpvlcp(x); mpvlcp(y);  { Value copy for mpinterval value parameter }
  mpinit(a); mpinit(b); mpinit(bnew);
                         { Initialization of local mpinterval numbers }
  a:= x; { Starting values for the AGM iteration }
  b:= y;
  WHILE a >< b DO BEGIN  { Iterate as long as a and b are disjoint }
    bNew:= sqrt(a*b);    { Geometric mean  }
    a:= (a+b)/2;         { Arithmetic mean }
    b:= bNew;
    { In each iteration step the convex hull of a and b is an }
    {   enclosure of AGM(x,y) = AGM(y,x).                     }
  END;
  AGM:= InitFunc;                     { Initialize function result }
  AGM:= a +* b;                           { Convex hull of a and b }
  AGM:= TempFunc;   { Result of function is only temporarily used }
  mpfree(a); mpfree(b); mpfree(bnew); { Free memory for local var }
  mpfree(x); mpfree(y);
END;

VAR
  a, b, res: mpinterval;  { Multi-precision intervals }
  nn, relerr: integer;
BEGIN
  mpinit(a); mpinit(b); mpinit(res); { Initialize mpinterval variables }
  writeln; writeln('*** Arithmetic-Geometric Mean Evaluation ***');
  writeln         ('***    to Arbitrary Verified Accuracy    ***');
  REPEAT
    writeln; write('Number of mantissa digits (base=2**32)  ?   ');
    read(nn); writeln;
    setprec(nn); { Precision setting }
    { An mpinterval is read by its bounds (without brackets) }
    write('a, b  (e.g. 1 1 for a and 2 2 for b): ');
    read(a, b); writeln;
    res:= AGM(a, b);
    IF nn < 7 THEN writeln(res);
    setprec(2);
    relerr:= 1 + expo( (res.sup -> res.inf) /> res.inf );
    writeln('Rel. error of enclosure <= 2**(', relerr, ')' );
  UNTIL false; { Infinite loop; stop with <ctrl> <c> }
END.
```

A sample output of this program is shown below. An enclosure for the arithmetic-geometric mean $AGM(1,2)$ is computed. The input `1 1` denotes the degenerate

interval [1,1] (point interval). A lower and an upper bound for the arithmetic-geometric mean as well as an upper bound for the relative error of the enclosure are given.

```
*** Arithmetic-Geometric Mean Evaluation ***
***    to Arbitrary Verified Accuracy    ***

Number of mantissa digits (base=2**32)  ?      3
a, b  (e.g. 1 1 for a and 2 2 for b):  1 1   2 2
 1.456791031046906869056249689 2E+000
 1.456791031046906869327300232 4E+000
Rel. error of enclosure <= 2**(-62)

Number of mantissa digits (base=2**32)  ?      6
a, b  (e.g. 1 1 for a and 2 2 for b):  1 1   2 2
 1.456791031046906869186432383265081974973863943219322690601E+000
 1.456791031046906869186432383265081974973863943223428057197E+000
Rel. error of enclosure <= 2**(-157)

Number of mantissa digits (base=2**32)  ?    100
a, b  (e.g. 1 1 for a and 2 2 for b):  1 1   2 2
Rel. error of enclosure <= 2**(-3165)
```

For example, using 100 mantissa digits for the multiple-precision interval arithmetic gives an enclosure of $AGM(1,2)$ with 3165 correct bits.

### 7.4.4 Computation of $\pi$ using Brent's Method

Algorithms for the computation of trigonometric functions in general make use of $\pi$ or some multiple of $\pi$. Especially for multiple-precision implementations of such routines guaranteed bounds of these constants with sufficient accuracy are needed. The computation of guaranteed bounds for elliptic integrals (see [195]) is also based on the availability of guaranteed bounds for $\pi$ with sufficient accuracy.

The following method is due to Brent [72]. Its rate of convergence is two. As with the AGM method all operations has to be performed with full length. The method is not a self correcting one.

Let $g_0 := \dfrac{\sqrt{2}}{2}$ and $a_0 := 1$. Define

$$t_n := \frac{1}{2} - \sum_{k=0}^{n} 2^{k-1} c_k^2$$

where

$$c_k := \sqrt{a_k^2 - g_k^2} = \frac{c_{k-1}^2}{4a_k} = a_{k-1} - a_k \ , \quad k = 0, 1, \ldots$$

and $g_n$ and $a_n$ are computed by the AGM iteration $AGM(g_0, a_0)$. Then

$$\frac{a_{n+1}^2}{t_n} < \pi < \frac{a_n^2}{t_n} \ , \quad n = 0, 1, \ldots \ .$$

leads to a sequence of enclosures of $\pi$. The rate of convergence is two. In each step of the iteration the number of correct mantissa digits is approximately doubled. In the following PASCAL-XSC program the calculations are done using a multiple-precision interval arithmetic.

```
PROGRAM BrentPi;
USE mp_ari, mpi_ari; { modules for multiple-precision arithmetic }
VAR
  a, b, x, y, t, np5 : mpinterval;
  pi_lb, pi_ub       : mpreal;
  nn, iter, err, errold    : integer;
BEGIN
  mpinit(a); mpinit(b); mpinit(x); mpinit(y); mpinit(t);
  mpinit(np5); mpinit(pi_lb); mpinit(pi_ub);
  write('Mantissa digits (base=2**32)? '); read(nn); writeln;
  setprec(nn);
  { nn mantissa digits with respect to base 2**32 are used }
  np5:= 0.5;
  a:= 1.0; b:= sqrt(np5); t:= 0.25; x:= 1.0;
  err:= 0;
  iter:= 0;
  REPEAT
    iter:= iter + 1; { number of actual iteration step }
    errold:= err;
    y:= a;
    a:= (a + b)/2; { arithmetic mean }
    b:= sqrt(y*b); { geometric mean  }
    y:= a - y;
    t:= t - x*y*y; { ti              }
    x:= x + x;
    pi_lb:= inf((a+b)*(a+b)/(4*t));
    pi_ub:= sup(a*a/t);
    { It is pi_lb < pi < pi_ub in each iteration step (see Brent) }
    err:= 1 + expo(pi_ub -> pi_lb);
    { upwardly directed rounded subtraction to get upper bound of }
    { exponent of the difference of upper and lower bound for pi  }
    writeln('Step ', iter:2, ':     Errorbound < 2**(', err, ')');
  UNTIL err > 2*(errold-1);     { no longer quadratic convergence }
  mpfree(np5); mpfree(pi_lb); mpfree(pi_ub);
  mpfree(a); mpfree(b); mpfree(x); mpfree(y); mpfree(t);
END.
```

The program produces the following output:

```
Mantissa digits (base=2**32)?
Step  1:     Errorbound < 2**(-4)
Step  2:     Errorbound < 2**(-13)
Step  3:     Errorbound < 2**(-31)
Step  4:     Errorbound < 2**(-67)
Step  5:     Errorbound < 2**(-140)
Step  6:     Errorbound < 2**(-285)
Step  7:     Errorbound < 2**(-575)
Step  8:     Errorbound < 2**(-1155)
Step  9:     Errorbound < 2**(-2315)
Step 10:     Errorbound < 2**(-4636)
Step 11:     Errorbound < 2**(-4763)
```

In each step the difference of the upper and lower bounds of the enclosure of $\pi$ is printed. The absolute value of the exponent (to base 2) is a lower bound of the correct number of bits reached so far. The 10-th iterate is an approximation of $\pi$

with 4636 correct bits. For the last step the number of correct bits is not doubled. This is due to the limited precision (in this example 150 mantissa digits with respect to the base $2^{32}$).

Other methods for the computation of $\pi$ may be found in [63], [64], [202] and [294].

### 7.4.5 Newton's Method for two Equations in two Unknowns

In this section we will discuss Newton's method, the classical example for a self correcting method. Under favorable circumstances the rate of convergence is two.

Newton's method applied to the system of nonlinear equations

$$h : \mathbb{R}^n \to \mathbb{R}^n, \quad h(z) = \begin{pmatrix} h_1(z_1, z_2, \ldots, z_n) \\ h_2(z_1, z_2, \ldots, z_n) \\ \vdots \\ h_n(z_1, z_2, \ldots, z_n) \end{pmatrix} \stackrel{!}{=} 0 \tag{7.12}$$

is an iteration designed to find a vector $\hat{z} \in \mathbb{R}^n$ such that

$$h(\hat{z}) = 0$$

simultaneously. The iteration formula (Newton's method) is given by

$$z^{k+1} := z^k - (h'(z^k))^{-1} \cdot h(z^k), \quad k = 0, 1, \ldots \tag{7.13}$$

with a starting vector $z^0$ which is sufficiently close to the root $\hat{z}$. The Jacobian matrix $h'(z)$ is defined by

$$h'(z) = \begin{pmatrix} \frac{\partial h_1}{\partial z_1} & \cdots & \frac{\partial h_1}{\partial z_n} \\ \vdots & \cdots & \vdots \\ \frac{\partial h_n}{\partial z_1} & \cdots & \frac{\partial h_n}{\partial z_n} \end{pmatrix}. \tag{7.14}$$

In case of two equations in two unknowns

$$h(z) = h(z_1, z_2) = \begin{pmatrix} h_1(z_1, z_2) \\ h_2(z_1, z_2) \end{pmatrix} =: \begin{pmatrix} f(x, y) \\ g(x, y) \end{pmatrix}$$

the inverse $R$ of the Jacobian matrix can be shown to be (if it exists)

$$(h'(x, y))^{-1} = \frac{1}{f_x g_y - g_x f_y} \begin{pmatrix} \frac{\partial g}{\partial y} & \frac{-\partial f}{\partial y} \\ \frac{-\partial g}{\partial x} & \frac{\partial f}{\partial x} \end{pmatrix} =: R \tag{7.15}$$

evaluated at $(x, y)$. This leads to a reformulation of the iteration formula in a componentwise form:

$$\left.\begin{array}{rcl} x^{k+1} & := & x^k - \dfrac{f\ g_y\ -\ g\ f_y}{d} \\ y^{k+1} & := & y^k - \dfrac{g\ f_x\ -\ f\ g_x}{d} \end{array}\right\} \quad k = 0, 1, 2 \ldots \tag{7.16}$$

with $d$ being

$$d\ :=\ f_x\ g_y\ -\ g_x\ f_y\ . \tag{7.17}$$

All function evaluations as well as the evaluations of the partial derivatives $f_x = \dfrac{\partial f}{\partial x}$, $f_y = \dfrac{\partial f}{\partial y}$, $g_x = \dfrac{\partial g}{\partial x}$ and $g_y = \dfrac{\partial g}{\partial y}$ have to be done at the previous approximate $(x^k, y^k)$.

#### 7.4.5.1 Verification Step

The verification step is based on Brouwer's fixed point theorem. If for an approximation $\tilde{z}$ of the root $\hat{z}$ of $h(z)$ and an interval vector $0 \in Z \in IR$ the condition

$$-R \cdot h(\tilde{z}) + \{I - R \cdot h'(\tilde{z} + Z)\} \cdot Z \subset Z \tag{7.18}$$

holds, then there exists exactly one root $\hat{z} \in \tilde{z} + Z$ with $h(\hat{z}) = 0$ [285]. The real matrix $R = (r_{ij})$ is an approximation for the Jacobian (7.14) of $h$, and $I$ denotes the identity matrix of corresponding order. All operations are interval operations. For two equations of two variables the condition can be reformulated in a componentwise manner:
If for an approximation $\tilde{z}\ =\ (\tilde{x},\ \tilde{y})$ of the root $\hat{z}\ =\ (\hat{x},\ \hat{y})$ of $h(z)$ and an interval vector $0 \in Z = (X,\ Y) \in IR$ the condition

$$\left.\begin{array}{rcl} -r_{11}f - r_{12}g + (1 - r_{11}f_x - r_{12}g_x)X - (r_{11}f_y + r_{12}g_y)Y & \subset & X \\ -r_{21}f - r_{22}g + (1 - r_{21}f_y - r_{22}g_y)Y - (r_{21}f_x + r_{22}g_x)X & \subset & Y \end{array}\right\} \tag{7.19}$$

holds, then there exists exactly one root $(\hat{x}, \hat{y}) \in\ (\tilde{x} + X,\ \tilde{y} + Y)$ with $h(\hat{x},\ \hat{y}) = 0$. Here, $f$ and $g$ have to be evaluated at $(\tilde{x}, \tilde{y})$ and the partial derivatives at $(\tilde{x} + X,\ \tilde{y} + Y)$ . Again, all operations are interval operations.

#### 7.4.5.2 PASCAL-XSC Listing using matrix/vector notation

We first give a simple implementation of the method described above using the predefined matrix/vector data types and matrix/vector operations for ordinary floating-point formats as they are supplied by the PASCAL-XSC modules `mv_ari` and `mvi_ari`. The computation of the inverse of an approximation to the Jacobian is done using predefined routines of the standard modules `lss` and `ilss`. The implementation is based on formulas (7.13) and (7.18). Such a simple matrix/vector implementation is up to now not available for multi-precision operations. Nevertheless, matrix/vector modules for multi-precision data types can be implemented.

```
PROGRAM newt_d2m;
{-------------------------------------------------------------}
{                              n        n                     }
{    Root of a function h: R    ---> R  will be enclosed      }
{           by an n-dimensional interval vector.              }
{                                                             }

    writeln('Interval iteration step: ', it);
    readln;
  UNTIL (y IN y_old) OR (it = max_it);
  IF y IN y_old THEN writeln('Verified enclosure: ', x + y);
END.
```

### 7.4.5.3 PASCAL-XSC Listing (Componentwise Form)

The PASCAL-XSC program given now is a straightforward implementation of the formulas (7.16), (7.17). In each step of the iteration the user is prompted to change the precision of the computations. For each step the new estimates of the roots are printed as well as the values of the component functions `f(x,y)` and `g(x,y)` evaluated at these new estimates. Under favourable circumstances the iteration gives a sequence of iterates which converges to the root quadratically. In this case the number of mantissa digits used may be doubled for succeding iteration steps.

```
PROGRAM Newt_Mp;
{------------------------------------------------------------}
{                                2        2                  }

#### 7.4.5.4 Numerical Example

As an example the following system of nonlinear equations is considered:

$$h(z) = \begin{pmatrix} f(x,y) \\ g(x,y) \end{pmatrix} := \begin{pmatrix} \exp(x+y) & - & c_1 \\ \exp(-x-y) & - & c_2 \end{pmatrix} \stackrel{!}{=} \begin{pmatrix} 0 \\ 0 \end{pmatrix} . \tag{7.20}$$

The parameters $c_1$ and $c_2$ are real quantities. The exact solution vector $\hat{z} \in \mathbb{R}^2$ of this system is given by

$$\hat{z} = \begin{pmatrix} \hat{x} \\ \hat{y} \end{pmatrix} := \begin{pmatrix} -0.5 \cdot \ln(c_1 \cdot c_2) \\ -0.5 \cdot \ln\left(\frac{c_1}{c_2}\right) \end{pmatrix} . \tag{7.21}$$

The program based upon matrix/vector operations given in Section 7.4.5.2 leads to the following sample output. The exact solution of the problem of the first run (here we use the parameters $c_1 := 1.125, c_2 = 0.125$) is $(-0.5\ln(9/64),\ -0.5\ln(9))^T = (\ln(8/3),\ -\ln(3))^T$. The program produces the following output:

```
Starting value for the root?        1   0
it: 1  h(actual approximate):
 6.509814806340075E-002
 1.755797187372329E+000
it: 2  h(actual approximate):
 9.975809295851401E-003
 4.410929666446322E-001
it: 3  h(actual approximate):
 3.597300542156345E-004
 5.667405156220262E-002
it: 4  h(actual approximate):
 5.156441406362067E-007
 1.337597591980932E-003
it: 5  h(actual approximate):
 1.063510390864053E-012
 7.939268307222136E-007
it: 6  h(actual approximate):
 2.775557561562891E-017
 2.799982468104645E-013
it: 7  h(actual approximate):
-2.775557561562891E-017
 0.000000000000000E+000
Interval iteration step: 1
Interval iteration step: 2
Verified enclosure:
[  9.808292530117260E-001,  9.808292530117266E-001]
[ -1.098612288668111E+000, -1.098612288668109E+000]
```

In the second run the parameters $c_1$ and $c_2$ are both set to the value 0.125. So the correct solution is given by $(-0.5\ln(1/64),\ 0)^T = (\ln(8),\ 0)^T$. The printout of the program is as follows:

```
Starting value for the root?  1  1       c1=c2=0.125
it: 1  h(actual approximate):
 2.918620196785084E-001
 3.847852820374753E-004
it: 2  h(actual approximate):
 8.197845189639522E-002
 5.898178638830132E-007
it: 3  h(actual approximate):
 1.428779943748035E-002
 1.391525783489556E-012
it: 4  h(actual approximate):
 7.083768377087463E-004
-2.775557561562891E-017
it: 5  h(actual approximate):
```

```
 1.992136587219973E-006
 2.775557561562891E-017
it: 6  h(actual approximate):
 1.587410758396857E-011
 2.775557561562891E-017
it: 7  h(actual approximate):
 2.775557561562891E-017
 2.775557561562891E-017
Interval iteration step: 1
Interval iteration step: 2
Interval iteration step: 3
Verified enclosure:
[  2.079441541679835E+000,  2.079441541679837E+000]
[               -4.9E-016,                1.3E-016]
```

Now the program using multiple-precision interval arithmetic described in paragraph 7.4.5.3 is executed to solve the same problem (parameters $c_1 = c_2 := 0.125$). For the final iteration steps of the real iteration the required precision of the calculations has been almost doubled in each step. This is adequate to the quadratic rate of convergence. The notation

```
Step: 1    |f|, |g| < 2**(-2)
```

means that after one step of the interation the magnitudes of both component functions $f$ and $g$ evaluated at the actual approximate are smaller than $2^{-2}$ (for the exact solution of the nonlinear system the component functions are 0 exactly).

```

y-coordinate:
  [-5.563E-309  , 5.181E-318  ]
```

The final enclosure is accurate to more then 300 decimal places. The correctness of the enclosure is verified by the algorithm itself (Brouwer's fixed-point theorem in combination with interval computations). Using the multi-precision interval logarithm supplied by the module `mpi_ari` we can verify that the $x$-coordinate displayed above is an enclosure of the first component $\ln(8)$ of the exact solution vector. The exact value of the second component is zero and indeed, the $y$-coordinate printed above is an enclosure of zero.

### 7.4.6 Arcsine Function

In this section we consider an implementation of the inverse sine function for multi-precision real arguments. The resulting multi-precision interval will contain the exact function value. The accuracy of the enclosure is related to the actual precision setting for the multi-precision point argument. We do not consider rounding errors by an a priory error estimation. Instead we use multi-precision interval arithmetic to find an enclosure of the truncated Taylor series. Only a bound for the relative approximation error caused by the truncation of Taylor's series has to be derived.

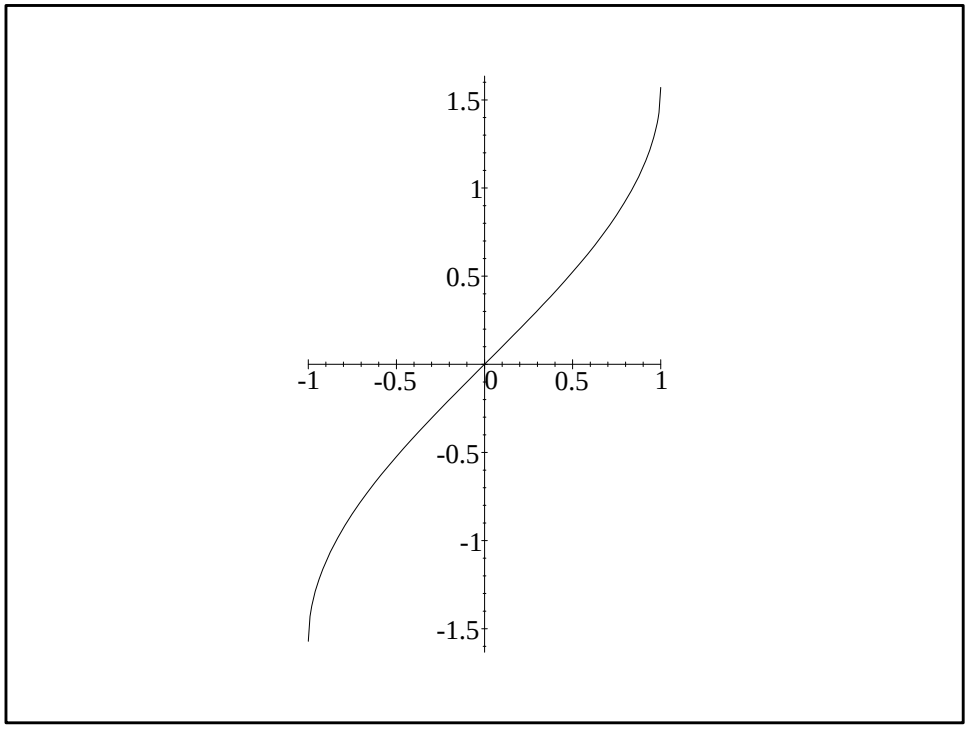

Figure 7.1: The inverse sine function $\arcsin(x)$

**Mathematical Background** The inverse sine function can be defined by

$$\arcsin x = \sum_{k=0}^{\infty} q_k \cdot x^{2k+1} =: s_\infty(x) \tag{7.22}$$

for $|x| \leq 1$. The first coefficients $q_k$ are given by

$$\begin{aligned} q_0 &:= 1, \\ q_1 &:= \frac{1}{2 \cdot 3}, \\ q_2 &:= \frac{1 \cdot 3}{2 \cdot 4 \cdot 5}, \\ q_3 &:= \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6 \cdot 7}, \\ q_4 &:= \frac{1 \cdot 3 \cdot 5 \cdot 7}{2 \cdot 4 \cdot 6 \cdot 8 \cdot 9}, \end{aligned}$$

and, in general, by

$$q_k := \frac{(2k)!}{(2^k k!)^2 \cdot (2k+1)} = \frac{1}{2k+1} \prod_{j=1}^{k} \frac{2j-1}{2j} \ . \tag{7.23}$$

They are all positive and the sequence $\{q_k\}_{k=0}^{\infty}$ is monotone decreasing (it holds $q_{k+1}/q_k < 1,\ k = 0, 1, \ldots$). Therefore, the truncated series

$$s_n = s_n(x) := \sum_{k=0}^{n} q_k \cdot x^{2k+1} \tag{7.24}$$

is monotone increasing in $x$ for values $x$ in the range $0 \leq x \leq 1$. Thus, for $[\underline{x}, \overline{x}] \subseteq [0, 1]$ it holds

$$\begin{aligned} \bigwedge_{x \in [\underline{x}, \overline{x}]} s_n(x) &= \sum_{k=0}^{n} q_k \cdot x^{2k+1} \\ &\in \left[ \sum_{k=0}^{n} q_k \cdot \underline{x}^{2k+1}, \sum_{k=0}^{n} q_k \cdot \overline{x}^{2k+1} \right] = [s_n(\underline{x}), s_n(\overline{x})]. \end{aligned} \tag{7.25}$$

Later on, the coefficients $q_{n+1}$ we will be computed by

$$q_{n+1} = q_n \cdot \frac{(2n+1) \cdot (2n+1)}{(2n+2) \cdot (2n+3)} \ . \tag{7.26}$$

The relative approximation error can be estimated using

$$|\arcsin x| \geq |x| \ . \tag{7.27}$$

We find

$$\begin{aligned}
\varepsilon_n(x) &:= \left| \frac{\arcsin(x) - x \cdot \sum_{k=0}^{n} q_k \cdot x^{2k}}{\arcsin(x)} \right| \\
&= \left| \frac{x}{\arcsin x} \right| \sum_{k=n+1}^{\infty} q_k \cdot x^{2k} \\
&\leq \sum_{k=n+1}^{\infty} q_k \cdot x^{2k} \\
&= q_{n+1} \cdot x^{2n+2} \sum_{k=n+1}^{\infty} \frac{q_k}{q_{n+1}} \cdot \frac{x^{2k}}{x^{2n+2}} \\
&= q_{n+1} \cdot x^{2n+2} \left\{ 1 + \underbrace{\frac{q_{n+2}}{q_{n+1}}}_{\in(0,1)} \cdot x^2 + \underbrace{\frac{q_{n+3}}{q_{n+1}}}_{\in(0,1)} \cdot x^4 + \ldots \right\} \\
&\leq q_{n+1} \cdot x^{2n+2} \sum_{k=0}^{\infty} x^2 = q_{n+1} \cdot x^{2n+2} \cdot \frac{1}{1-x^2}
\end{aligned} \tag{7.28}$$

This bound is valid for $x \in (-1, 1)$. Here the geometric series with common ratio $x^2 < 1$ has been applied. For $[\underline{x}, \overline{x}] \subseteq [0, 1/2]$ it holds

$$\bigwedge_{x \in [\underline{x}, \overline{x}]} \varepsilon_n(x) \overset{(7.28)}{\leq} q_{n+1} \cdot \frac{4}{3} \cdot x^{2n+2} \leq \frac{4}{3} \cdot q_{n+1} \cdot \overline{x}^{2n+2} \tag{7.29}$$

The right hand side of (7.29) is an overestimation of the maximum relative truncation error. The special values $x \in \{-1,\ 0,\ 1\}$ will be treated in a correct way as may be seen by the source code of the program module shown in Paragraph 7.4.6.3. In the case $x = 0$ the point interval [0,0] will be returned. In the remaining cases enclosures for $\pm\frac{\pi}{2}$ depending on the sign of $x$.

### 7.4.6.1 Argument Reduction

The argument reduction process uses the relations

$$\arcsin(x) = -\arcsin(-x) \tag{7.30}$$

as well as

$$\arcsin(x) = \frac{\pi}{2} - 2 \cdot \arcsin\sqrt{\frac{1-x}{2}} \tag{7.31}$$

The first relation is used if $x < 0 \quad (\Rightarrow -x > 0)$ and the second one is used if $|x| > 1/2 \quad (\Rightarrow \sqrt{(1-|x|)/2} \in [0, 1/2])$. Thus the final reduced argument $t$ lies in the basic range $0 \leq t \leq 1/2$. In this range (7.29) can be used.

#### 7.4.6.2 Algorithmic Description

We first discuss an algorithm to compute a lower bound of $\arcsin(x)$.

## Algorithm 7.1: Asin $(x)$ {function}

$\varepsilon := 10^{-k}$, $k$ depends on the actual precision setting when entering this function.
neg:= $x < 0$ {neg=true if the argument is smaller then zero}
**if** neg **then**
  $[r] := -x$
**else**
  $[r] := x$
reduc := $[r] > 0.5$
**if** reduc **then** $[r] := \sqrt{\frac{1-[r]}{2}}$ {argument reduction}

$n := 0$
**repeat** {until truncation error is small enough}
  $[s] := s_n([r]) = \sum_{k=0}^{n} q_k [r]^{2k+1}$ {truncated Taylor series}
  RelErr:= $\triangle(\frac{4}{3} \cdot q_{n+1} \cdot \overline{r}^{2n+2})$ { see formula (7.29)}
  {$\triangle$ denotes the upwardly directed rounding}
  $n := n + 1$

**until** RelErr$< \varepsilon$

$[s] := [s] \cdot [1, 1 + \text{RelErr}]$ {take truncation error into account}

**if** reduc **then**
  $[s] := [\frac{\pi}{2}] - 2 \cdot [s]$ {apply (7.31)}
**if** neg **then**
  $[res] := -[s]$ {apply (7.30)}
**else**
  $[res] := [s]$

**return** Asin $:= [res]$

#### 7.4.6.3 Program Code

The following module `mpasin.p` implements Algorithm 7.1.

```
MODULE mpasin;
```

```
{ This module implements the inverse sine functuion called asin(x)   }
{ x being a multi-precision real number. The result will be a multi- }
{ precision interval which contains the exact function value.        }

USE i_ari;              { 'normal' interval arithmetic }
USE mp_ari, mpi_ari;    { multi-precision arithmetics  }

GLOBAL FUNCTION asin(x: mpreal): mpinterval;
{ The name of the intrinsic multi-precision arcsine function is }
{ arcsine. Therefore we use the different name asin.            }
VAR
  RelErr: real;
  r, rr, rpot, s, e, q_n: mpinterval;
  c, err, ir, irpot, iq_n: interval;
  n: integer;
  neg, reduc: boolean;

BEGIN
  mpvlcp(x);
  mpinit(r); mpinit(rr); mpinit(rpot); mpinit(s);
  mpinit(e); mpinit(q_n);

  { Check whether x is a valid argument in the reange [-1, 1] }
  IF (x<-1) OR (1<x) THEN BEGIN
    writeln('*** Invalid argument in asin(x) in module mpasin.p!');
    n:= n DIV 0; { force program termination by a divide by zero }
  END;

  RelErr:= exp(-getprec*9*ln(10.0));
  { A precision setting of getprec corresponds to roughly 8*getprec }
  { decimal digits. So 10**(-9*getprec) is used as error bound for  }
  { the relative approximation error.                               }

  setprec(getprec+1);  { one guard digit with respect to base 2**32 }
  neg:= x < 0;

  mpfree(q_n); mpfree(e);   { deallocate mp-variables }
  mpfree(r); mpfree(rr); mpfree(rpot); mpfree(s);
  mpfree(x);
END;

BEGIN  { body of the module mpasin.p }
  { nothing to inizialize }
END.
```

A corresponding driver program is given now:

```
PROGRAM asintst;
{***    Driver program for the module mpasin.p   ***}
USE mp_ari, mpi_ari;   { multi-precision arithmetic }
USE mpasin;            { new module                 }

VAR i: integer;
    x: mpreal;         { multi-precision point argument  }
BEGIN
  mpinit(x);  { initialize mp-variable }
  FOR i:= 1 TO 5 DO BEGIN
    setprec(2+i); { increase actual precision setting }
    write('Argument for arcsin:  ');
    read(x);
    writeln;
    writeln('Argument: ');
    writeln(x);
    { The number of decimal digits shown in the output depends on }
    {   the actual precision setting. }
    writeln('Actual precision setting: ', getprec:0);
    { The function getprec gives the number of mantissa digits }
    {   with respect to base 2**32.                            }
    writeln('asin(x)  (lower bound, upper bound): ');
    writeln(asin(x));
   END;
   mpfree(x);  { deallocate mp-variable }
END.
```

The program will produce the following output:

```
Argument for arcsin:   0.125
Argument:
 1.25000000000000000000000000E-001

```

Here we can immediately see that the accuracy of the enclosure depends on the precision setting done by `setprec()` in the driver program `asintst.p` .

### 7.4.7 Creation of Constants for Interval Functions

In this section we will give some hints how to compute constants (for example coefficients of polynomials, reduction constants for function evaluations, values like $\ln(2), \ln(10)$, $\pi$, and so on) to maximum accuracy with respect to the IEEE double floating-point format or even with an accuracy beyond the accuracy associated with that data format. In the latter case a sequence of floating-point values will be generated, the sum of which is very close to the exact value of the desired constant, i. e. we will compute a kind of staggered representation (see also chapter 5.3.5).

Let us first compute $\ln(10) = 2.302585\ldots$ to 53 bit accuracy. Our goal is to find $t = \square(\ln(10))$. As usual, the symbol $\square$ denotes the operation round to the nearest IEEE double number. Of course we could take the value of $t$ (the correct bit sequence) from a table. Due to the hidden bit technique of the IEEE data format and exponent considerations cumbersome bitmanipulations would be necessary. Moreover, constants which are not so common can in general not be found in such a table.

Due to the availability of a lot of mathematical functions for multi-precision real and interval arguments in PASCAL-XSC it is often very easy to find the floating-point representation of a real value with maximum accuracy. We only have to round the bounds of a multi-precision enclosure of the desired value to ordinary floating-point numbers. This can be done using the overloaded assignment operator `:=` . This operator performs a conversion (round-to-nearest!) from a multi-precision value to a floating-point number. If the conversion of the lower bound of the enclosure is equal to the conversion of the upper bound, it follows that the converted lower bound is the round to nearest value of the constant.

The following listing shows a PASCAL-XSC program for the computation of the correctly rounded value of ln(10):

```
PROGRAM ln10;
USE i_ari,   { interval arithmetic }
    mp_ari,  { real multi-precision arithmetic }
    mpi_ari, { interval multi-precision arithmetic }
    x_real;  { hexadecimal printing of real numbers (IEEE convention) }

VAR
  Ln10Long: mpinterval; { Multi-prec. enclosure of ln(10) }
  Ln10: real;           { ln(10) round to nearest         }
  a, b: real;           { Auxiliary real values           }
BEGIN
  setprec(2);
  mpinit(Ln10Long);
  REPEAT
    setprec( getprec+1 );  { Increase precision setting                }
    Ln10Long:= ln( _mpinterval(10) );
    a:= inf(Ln10Long);  { Lower bound round to the nearest IEEE number }
    b:= sup(Ln10Long);  { Upper bound round to the nearest IEEE number }
  UNTIL  a = b;
  Ln10:= a;                        { a = b = round to nearest( ln(10) ) }
  writeln('Ln(10) round to nearest: ');
  writeln( Ln10, '   IEEE notation: ', Ln10:'X');
  writeln('Precision setting used: ', getprec:1);
  mpfree(Ln10Long);
END.
```

The output of this program is as follows:

```
Ln(10) round to nearest:
 2.302585092994046E+000   IEEE notation: 40026BB1BBB55516
Precision setting used: 3
```

The next program demonstrates how to approximate a transcendental number (here $\pi$) to high accuracy using a sum of floating point values:

```
PROGRAM LongConst;
USE i_ari,   { interval arithmetic }
    mp_ari,  { real multi-precision arithmetic }
    mpi_ari, { interval multi-precision arithmetic }
    x_real;  { hexadecimal printing of real numbers (IEEE convention) }

CONST kMax = 15;   { number of summands, upper bound of loop variable }

VAR PiDown,  { high prec. lower bound of Pi }
    PiUp:    { high prec. upper bound of Pi }
      ARRAY[1..kMax] OF real;
```

```
    x, Pi: mpinterval;  { auxiliary multi-prec. numbers }
    y: interval;        { used for rounding purposes    }
    k: integer;
BEGIN
  setprec( 2*kMax+2 );
  mpinit(x);   { Initialize multi-prec. variables }
  mpinit(Pi);
  x:= 1;             { arctan(1) = Pi/4 }
  Pi:= 4*arctan(x); { Enclosure of Pi  }
  x:= Pi;            { Initialize x with an enclosure of Pi }

  writeln(' k          PiDown (dec)        PiDown (hex)      PiUp (hex)');
  writeln('=============================================================');
  FOR k:= 1 TO kMax DO BEGIN
     y:= x;  { round multi-prec. variable x to an ordinary interval }
     PiDown[k]:= inf( y );  { take lower bound of y as new summand  }
     IF k < kMax THEN
        PiUp[k]  := inf( y )
     ELSE { Only the last summands of PiDown and PiUp are different }
        PiUp[k] := sup( y );
     writeln(k:2, '  ', PiDown[k], '  ',
                                    PiDown[k]:'X', '  ', PiUp[k]:'X' );
     x:= x - PiDown[k];
     IF 0 IN x THEN writeln('No more significant digits!');
  END;
  mpfree(x);    { Deallocate multi-prec variables }
  mpfree(Pi);
END.
```

The sum of the floating-point values in column PiDown is a high precision lower bound whereas the sum of the quantities in column PiUp is a high precision upper bound for the constant $\pi$:

```
 k          PiDown (dec)        PiDown (hex)      PiUp (hex)
============================================================

```

The last example in this section deals with the representation of floating point quantities by quotients of exactly representable decimal numbers. The numerator will be an integer value and the denominator a suitable power of 2. Such representations can be used to specify polynomial coefficients, reduction constants, best possible approximations of transcendental constants and so on by decimal strings. No hexadecimal input is necessary. The compiler transforms automatically and without any rounding error the numerator as well as the denominator in the IEEE floating-point format. The final division is nothing else but a shift. It also will be

done error free. The program, as it is shown here, does not resort to multi-precision calculations. However, multi-precision calculations will be used in general to find a good approximation for the exact constant.

```
PROGRAM quot;
{ Computation of p and q with p/q = round downwards(ln10) }

USE x_real,    { hexadecimal printing of real numbers }
    i_ari;     { interval arithmetic                  }

VAR c: real;   { Constant to be expressed as p/q }
    p: real;   { numerator                       }
    q: real;   { denominator (power of two)      }
    shift: integer; { Exponent of denominator    }
BEGIN
  c:= inf( ln(intval(10)) ); { Constant to be converted }
  { The constant c usually comes from a multi-prec. computation }
  write('Constant c: ', c, ' (dec)  ', c:'X', ' (IEEE)');
  shift:= 53 - expo(c);    { Reals have 53 mantissa bits }
  { Scaling of c by 2**shift results in an integer value }
  { 0.5 <= c < 1 ==> expo(c) = 0  }
  writeln( '  Exponent of c: ', expo(c) );
  writeln( '  p = c * 2**', shift:2 );
  writeln( '  q =     2**', shift:2 );
  p:= c*power(2, shift); { transform const. c to integer }
  q:=   power(2, shift); { denominator = 2**(52-expo(c)) }
  writeln( 'Numerator p   (down): ',   p:50:15:-1);
  writeln( '              (up  ): ',   p:50:15:+1);
  writeln( 'Denominator q (down): ',   q:50:15:-1);
  writeln( '              (up  ): ',   q:50:15:+1);
  { Check  whether p/q is exactly equal to c in all rounding modes }
  IF c - intval(p)/q <> 0 THEN
    writeln('*** E R R O R ***')
  ELSE BEGIN
    writeln('It holds: ');
    writeln('  Floating-point number c = p/q without rounding error!');
  END;
END.
```

The output of the program shows the representation of the best possible lower bound (IEEE double format) of ln(10):

```
Constant c:  2.302585092994045E+000 (dec)  40026BB1BBB55515 (IEEE)  Expo-
nent of c: 2
  p = c * 2**51
  q =     2**51
Numerator p   (down):                  5184960683398421.000000000000000
              (up  ):                  5184960683398421.000000000000000
Denominator q (down):                  2251799813685248.000000000000000
              (up  ):                  2251799813685248.000000000000000
It holds:
  Floating-point number c = p/q without rounding error!
```

## 7.5 Concluding Remarks

Due to the operator concept of PASCAL-XSC and the overloading of functions (generic functions) programs using the modules for multiple-precision real and

multiple-recision interval arithmetic are easy to develop easy to read and easy to debug. At the present state, variables of the multiple-precision data types have to be initialized (function `mpinit( )`). Also the result of a multiple-precision function or operator has to be initialized and the temporary flag has to be set 'by hand'. Nevertheless, we hope that the numerous examples given above show how easy and straightforward programs for multi-precision computations can be developed using the modules `mp_ari` and `mpi_ari`.

A great advantage of programs written in PASCAL-XSC is the portability of these programs. In the meantime PASCAL-XSC is available for a great variety of computers. Going to a PASCAL-XSC system on another computer no changes have to be made at the source code of the programs. Also the numerical results are bitwise the same. This statement holds true for multi-precision computations in PASCAL-XSC.

## 7.6 Exercises

**Exercise 7.1** The quantity

$$q_1 := e^{\pi\sqrt{163/9}}$$

starts with the decimal expansion

$$q_1 = 640320.00000000\ldots\ .$$

Try to show by computation whether $q_1$ is an integer.

The same question arises for

$$q_2 := e^{\pi\sqrt{163}}\ .$$

What is the correct value of $q_2$ up to 50 decimal places? In Brent [73] a Fortran 77 program is printed which computes the quantities above using the multiprecision package described in the same paper. Compare your PASCAL-XSC source code with the one given by Brent.

**Exercise 7.2** The argument reduction for the trigonometric functions is usually done by a subtraction of the form

$$x - k \cdot \frac{\pi}{2} \tag{7.32}$$

Here the integer value $k \in Z$ is to be chosen in such a way that the difference (7.32) will be a quantity between $-\pi/4$ and $\pi/4$. Compute for the real value

$$x = x_{\text{bad}} := 6381956970095103 \cdot 2^{797} \tag{7.33}$$

the appropriate $k = k_x$. How many decimal digits has $k_x$? Compute for the values $x_{\text{bad}}$ and $k = k_x$ an enclosure of the difference (7.32). Compute an enclosure of $\cos(x_{\text{bad}})$. What is the best possible enclosure of $\cos(x_{\text{bad}})$ with IEEE double

numbers as bounds? Verify that $x_{\text{bad}}$ is exactly representable in the IEEE double floating-point format. How many bits cancel due to the process of argument reduction? To which accuracy $\pi/2$ has to be known to get an accurately reduced argument to say 53 bits?

Remark: The value $x_{\text{bad}}$ given above is an IEEE double number which comes closest to the set

$$M := \{ k \cdot \frac{\pi}{2} \mid k \in Z,\ k \neq 0 \}. \tag{7.34}$$

I. e. if we denote the set of all IEEE double numbers by $S$ it holds (cf. [258])

$$\text{dist}(S \backslash \{0\},\ M) = \text{dist}(\ x_{\text{bad}},\ M)\ . \tag{7.35}$$

**Exercise 7.3** Show by induction relation (7.7) on page 214 concerning Fibonacci numbers.

## 7.7 References and Further Readings

There exists a lot of literature about multiprecision arithmetics. As a main reference see Knuth [186]. One of the most frequently used and most popular package is Brents package [73, 75]. Newer articles are [28, 29, 126, 138, 202, 203, 304]. Some of the described packages are available via anonymous ftp.

# Chapter 8

# (Pseudo) Random Number Generators

In this paragraph we present some random number generators. PASCAL-XSC intrinsically does not provide any random number generator. Especially when testing implementations of algorithms for mathematical functions such generators are a very useful tool. But of course they are also useful in many other applications.

## 8.1 Remarks on Linear Congruential Generators

We only will provide pseudo random number generators which are based on a recurrence of the form

$$r_{j+1} = a \cdot r_j + c \pmod{m} \tag{8.1}$$

Such gererators are called linear congruential generators. They generate a sequence of integers $r_1, r_2, r_3, \ldots$, each between 0 and $m-1$. Here the integer $m$ is called the modulus and $a$ and $c$ are positiv integers called the multiplier and the increment respectively. The recurrence (8.1) will eventually repeat itself, with a period that is obviously no greater than $m$. If $m, a$, and $c$ are properly chosen, then the period will be of maximal length. In that case, all possible integers between 0 and $m-1$ occur at some point, so any initial 'seed' is as good as any other.
The congruential method has the advantage of being very fast, requiring only a few operations per call hence its almost universal use. It has the disadvantage that it is not free of sequential correlation on successive calls. If $k$ random numbers at a time are used to plot points in $k$ dimensional space (with each coordinate between 0 and 1), then the points will not tend to 'fill' up the $k$-dimensional space, but rather will lie on $(k-1)$-dimensional 'planes'. There will be at most about $m^{\frac{1}{k}}$ such planes. If the constants $m, a$ and $c$ are not very carefully chosen, they will be many fewer than that. Figures 8.1, 8.2, 8.3 shows the result using the (bad) generator

$$r_{j+1} = 24298 r_j + 99991 \pmod{199017} \tag{8.2}$$

to generate points in $\mathbb{R}^3$. Figure 8.1 gives the impression of rather randomly generated points. But if we change the orientation appropriately we see large regions which do not contain any point generated by our random number generator. All points lie on only 4 planes (see Figure 8.2 and Figure 8.3).

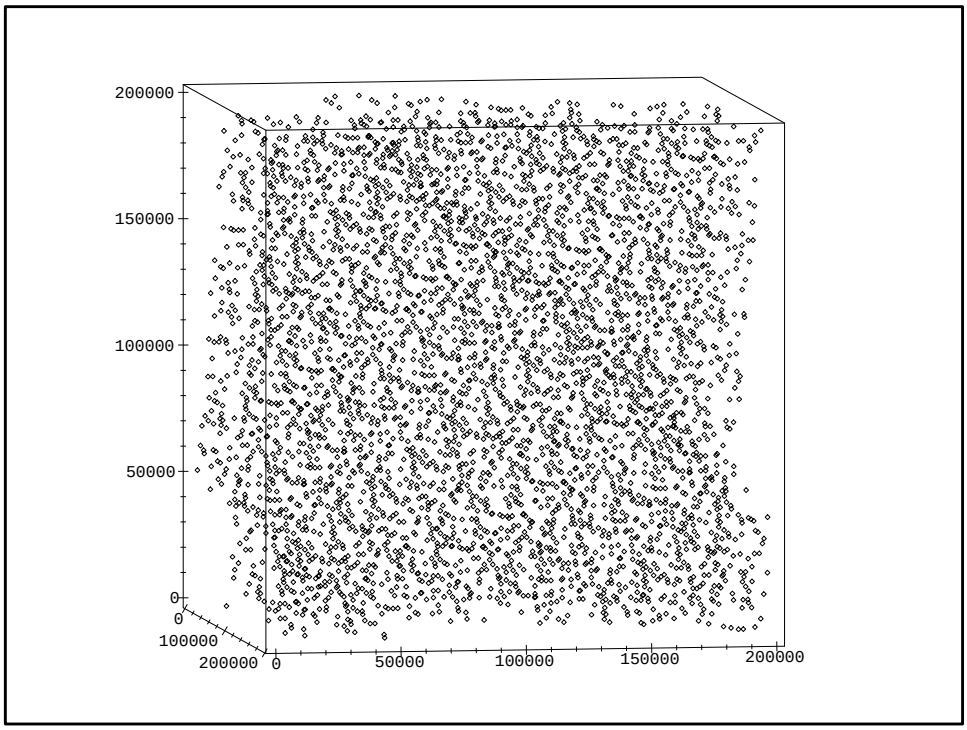

Figure 8.1: Random points generated by the recurrence (8.2)

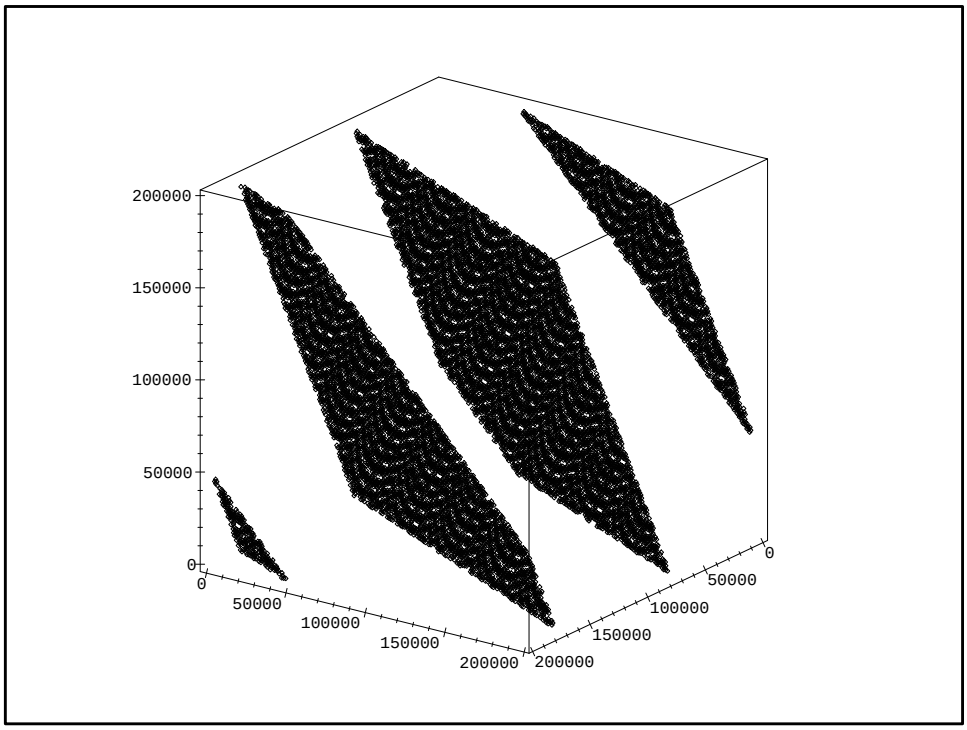

Figure 8.2: Random points generated by recurrence (8.2) lie on only four planes

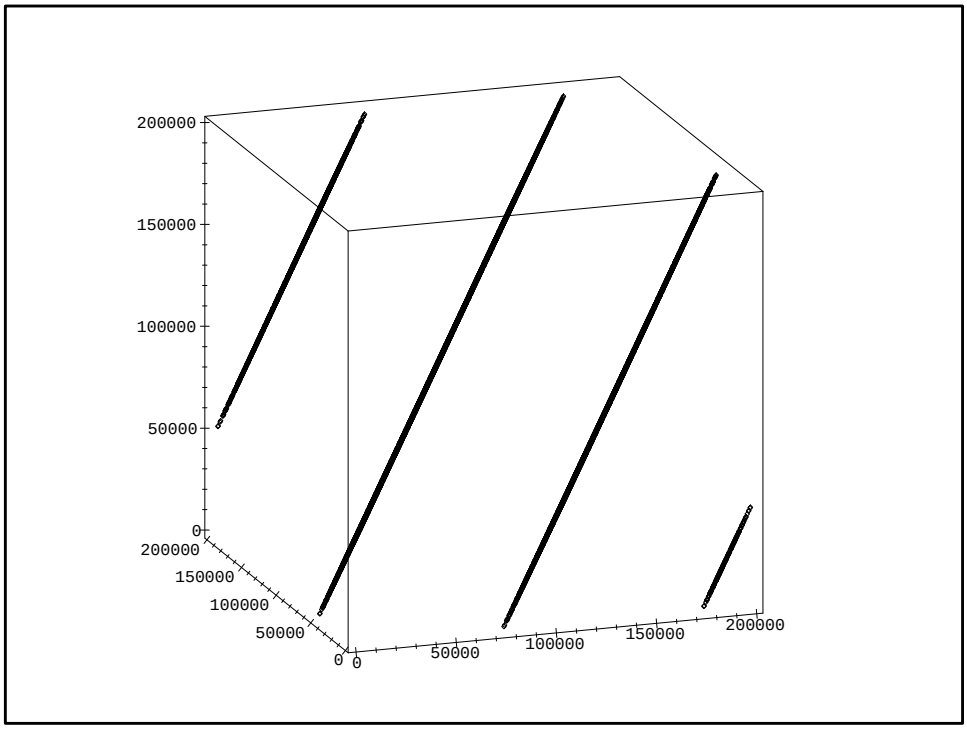

Figure 8.3: Random points generated by the recurrence (8.2) (one additional sight)

## 8.2 Algorithms

We first give the algorithm for the 'Minimal Standard' generator as it was introduced by Park and Miller [264] and used in [265]. This generator has a vanishing increment $c = 0$. It is given by

$$r_{j+1} = 7^5 \cdot r_j \pmod{2^{31} - 1}, \quad \text{i.e. ,} \tag{8.3}$$

$$m := 2147483647,\ a := 16807,\ c := 0. \tag{8.4}$$

Of course, $r_0 = 0$ must never be allowed as initial seed. For any other initial seed the period of (8.3) is $2^{31} - 2 \approx 2 \cdot 10^9$. To avoid products (e.g. $a \cdot (m-1)$) larger than the maximum value of a 32-bit integer, we use Schrage' s algorithm [298] for multiplying to 32-bit integers modulo a 32-bit constant, without using any intermediates larger than 32 bits:
If in the approximate factorization of the multiplier $m$,

$$m = a \cdot q + b \quad (q := \text{trunc}(\frac{m}{a}),\ \ r := m \bmod a, \text{the values } a \text{ and } m \text{ are given})$$

$b$ is smaller than $q$ and $0 < z < m - 1$, it follows that all intermediate results are representable, i.e. it holds

$$a \cdot (z \bmod q),\ \ b \cdot \text{trunc}(\frac{z}{q}) \in \{0, \ldots, m-1\},$$

and

$$a \cdot z \bmod m = \begin{cases} a \cdot (z \bmod q) - b \cdot \mathrm{trunc}\dfrac{z}{q} & \text{if this value is} > 0\ , \\ a \cdot (z \bmod q) - b \cdot \mathrm{trunc}\dfrac{z}{q} + m & \text{otherwise.} \end{cases}$$

For the Minimal Standard generator the values $q := 127773$ and $b := 2836$ are used.

**Algorithm 8.1:** rand0 {function, no argument}

{Fixed values: $a = 16807, m = 2147483647, w = \dfrac{1}{m}, q = 127773, b = 2836$ }
{ $rk$ (initialized by seed = 123456789) will be changed at each call! }

$j := rk$ div $q$
$rk := a \cdot (rk - j \cdot q) - b \cdot j$
**if** $rk < 0$ **then** $rk := rk + m$

**return** rand0:= $rk \cdot w$

The algorithm given here does not allow an initial seed being supplied by the user. In the PASCAL-XSC program code an additional procedure `seed` is provided. This global procedure can be used to initialize the random number generator. Algorithm rand0 is satisfactory for the majority of applications. Some (in most cases minor) disadvantages (see Press [265], page 279) will be removed by the generators implemented in the modules `rand1` and `rand2`. For the generators we will not give an algorithmic description. We only will give their PASCAL-XSC code in the next section. They are adaptations of the programs given in [265] to PASCAL-XSC. For our routines the naming of variables given there is adopted.

## 8.3 Program Code

The first module called `rand0` implements the Minimal Standard generator due to Park and Miller:

```
MODULE rand0;
{------------------------------------------------------------------}
{ "Minimal" random number generator of Park and Miller. It returns }

If very long random sequences are needed the random number generator implemented in the module `rand2` should be used. Here we realize an algorithm due to L'Ecuyer [225] who has given a good way of combining two different sequences with different periods so as to obtain a new sequence whose period is the least common multiple of the two periods. As in the previous module `rand1` an additional shuffle is performed.

The next module called `random` uses one of the previous modules `rand0`, `rand1` or `rand2` to generate its random values. Notice that the random number generators in each of this modules are called `rand` and the procedure to initialize the corresponding random number generator is always called `seed`. To choose the appropriate generator one has to activate the correct use clause at the beginning of the module `random`. By default the module `rand0` is included. So the fastest generator (the Minimal Standard generator wihout shuffling) is called.

```
MODULE random;
USE GLOBAL
{ rand0; { random number generator is used }
{-------------------------------------------------------------------}
{ "Minimal" random number generator                                 }

```

We now list a driver program which calls the random number generator chosen by the activated use clause in the module `random`. The program generates random numbers in a specified range, subintervals with randomly generated bounds and complex numbers with randomly generated real and imaginary parts. Uniformly as well as logarithmically distributed numbers are generated.

```
PROGRAM RanTst;
{ Driver program for random number generators }
USE random;

USE i_ari, c_ari;
VAR
  x, RandomInterval: interval;
  k, kmax: integer;
  u, v: complex;

BEGIN
  kMax:= 10;  { Upper bound of loops }
  seed(35);   { Initialization of the random number generator }

  writeln('Uniformly distributed random numbers in the range -41..20:');
```

```
  FOR k:= 1 TO kMax DO BEGIN
    writeln( Rand(-41,20):10:3);
  END;

  writeln;
  writeln('Uniformly distributed complex random numbers: ');
  u:= compl(-1,11); v:= compl(2,12);
  writeln('u: ', u);
  writeln('v: ', v);
  { Generate complex random numbers with real part in the range }
  {   Re(u)..Re(v) = -1..2  and imaginary part in the range     }
  {   Im(u)..Im(v) = 11..12.                                   }
  FOR k:= 1 TO kMax DO BEGIN
    writeln( Rand(u, v));
  END;

  writeln;
  writeln('Log. distributed random numbers in the range 0.5..99999:');
  FOR k:= 1 TO kMax DO BEGIN
    writeln( RandLn(0.5, 99999):10:3);
  END;

  writeln;
  x:= intval(-855.9 , 909);  { Subintervals of x will be generated }
  writeln('Subintervals of [', x.inf:10:3, ', ', x.sup:10:3, ']:' );
  FOR k:= 1 TO kMax DO BEGIN

## 8.5 Exercises

**Exercise** Generate a sparse matrix $A$ and a right hand side vector $b$ with entries being uniformly distributed random numbers. Solve the system $A \cdot x = b$ using the sparse linear system solver discussed in Chapter 2.

## 8.6 Refernces and Further Readings

Two fundamental sources are [186] and [265]. Some original work may be found in [225, 264, 298].

# Chapter 9

# Composition of Interval Functions

## 9.1 Introduction

In the following paragraphs we will present different methods for the computation of interval functions. Here an interval function means the extension of a real valued function $\varphi : D \subset \mathbb{R} \longrightarrow \mathbb{R}$ which is continuous on every closed interval in its domain $D$ to interval arguments $[x] \subset D$ by the definition

$$\varphi([x]) := \{\varphi(x) \mid x \in [x]\}.$$

In general it is not possible to compute the exact range of $\varphi$ over $[x]$. But it is guaranteed that the computed range contains $\varphi(x)$ for all $x \in [x]$. Of course the goal is a sharp enclosure of the exact range of function values.

Many elementary mathematical functions are monotone at least in some subranges of $D$. If we are able to enclose $\varphi(x)$ for point input data $x \in D$ we can construct an enclosure of $\varphi([x]) = \varphi([\underline{x}, \overline{x}])$ using enclosures of $\varphi(\underline{x})$ and $\varphi(\overline{x})$. For example $\exp([x]) = [\exp(\underline{x}), \exp(\overline{x})]$ and $\operatorname{arcoth}([x]) = [\operatorname{arcoth}(\overline{x}), \operatorname{arcoth}(\underline{x})]$. So we are faced with the basic problem how to compute strict lower and upper bounds of the value of $\varphi(x)$ at points $x$. The methods we will describe here are more or less based on standard argument reduction techniques and Taylor polynomial evaluations. We also give an implementation of an accurate table lookup agorithm.

The most simple method to get an enclosure of point values will be the computation of Taylor polynomials (partial sums of series expansions) in interval arithmetic. In this way roundoff errors are bounded rigorously. Similarly, the argument reduction, though applied to thin intervals (points), is carried out in interval arithmetic. Adding to the enclosure of the Taylor polynomial the (in general small) approximation error term and performing the result adaptation again in interval arithmetic yields rigorous bounds for $\varphi(u)$, $u \in \{\underline{x}, \overline{x}\}$ .

The method described so far has several disadvantages:

- due to interval computations the runtime of such routines is not optimal.
- the degrees of the Taylor polynomials are in general not as low as the degree of corresponding polynomials coming from Chebyshev approximations or even being (almost) best approximations.
- accurate argument reduction techniques using scalar products which can be computed in PASCAL-XSC by only one rounding may improve the numerical quality of the computed enclosures significantly.

The main reason for two different implementations is the significant loss of performance in case of a posteriori error estimations as compared with implementations using a priori error estimations (see the discussion for the exponential routine $\exp(x)$).

On the other hand, the implementation using a posteriori error estimations can be applied to other *real* data formats including multiple presicion formats (see Section 7.4.6 and [190]) whereas the implementation using a priori error estimations is restricted to the *real* format as specified in Section 9.2 . In the subsequent paragraphs we will discuss these problems in more detail.

For functions which are not monotone additional considerations have to be applied. As examples, we will discuss the sine function as a periodic function with an irrational period length and the power function as a function depending on two arguments. The example of the interval power function is mainly intended to give an expression of what has to be done to handle real and imaginary parts (they can be interpreted as functions of two real variables) of complex interval functions. For the implementation of complex interval functions with high accuracy refer to [68], [70] and [188].

Before we treat the implementation of (interval) functions in more detail we discuss the underlying real data format of PASCAL-XSC.

## 9.2 PASCAL-XSC Data Type *real*

The material discussed in this section is mainly taken from the PASCAL-XSC User's Guide [262].

The PASCAL–XSC data type *real* consists of all floating-point numbers and special values which are specified by the IEEE standard [143] for the double floating-point number format. A variable of type *real* is 64 bits long and requires eight bytes of storage. In Figure 9.1, a sketch of the IEEE double floating-point data format is given.

The largest and the smallest positive real value representable by the data type *real* are denoted by *maxreal* and *minreal*, respectively. The constants *maxreal* and *minreal* are defined in module `x_real`.

The floating-point number format uses a binary representation (base B=2) of the mantissa digits. There is one implicitly defined hidden bit in the representation of normalized and denormalized numbers, thus making a total length of the mantissa $m$ of 53 bits. The exponent field $e$ occupies 11 bits. For normalized floating-point numbers according to the notation in Figure 9.1, the range of exponent values is specified by the maximum exponent $e_{max} = 2046 - 1023 = 1023$ and the minimum exponent $e_{min} = 1 - 1023 = -1022$. The sign field $s$ occupies 1 bit.

**Example** The decimal number 0.1 can be written in the form

$$0.1 = \sum_{k=1}^{\infty} ( 2^{-4k} + 2^{-(4k+1)} ) \quad .$$

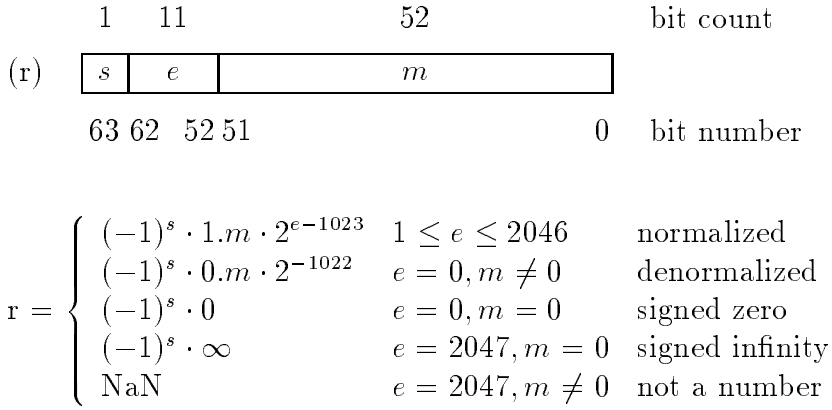

Figure 9.1: IEEE double floating-point format

| Hexadecimal Representation | Decimal Value |
|---|---|
| `0000000000000001`<br>*minreal* | $4.9406564584124654 \cdot 10^{-324}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $-\infty$ yields 0.0. |
| `7FEFFFFFFFFFFFFF`<br>*maxreal* | $1.7976931348623158 \cdot 10^{308}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $+\infty$ yields $+\infty$. |

Figure 9.2: *real* constants *minreal* and *maxreal*

| Hexadecimal Representation | Rounding Mode | Decimal Value |
|---|---|---|
| `3FF0000000000000` | exact | 1.0 |
| `BFF0000000000000` | exact | $-1.0$ |
| `3FE0000000000000` | exact | 0.5 |
| `3FB999999999999A` | $\square$ | 0.1 |
| `3FB9999999999999` | $\nabla$ | 0.1 |
| `3FB999999999999A` | $\triangle$ | 0.1 |
| `400921FB54442D18` | $\square$ | $\pi$ |
| `3FF921FB54442D18` | $\square$ | $\pi/2$ |

Figure 9.3: Some decimal values and their IEEE representation

Thus, the value 0.1 is not exactly representable in any binary floating-point system. Its *infinite* binary representation is $0.000\overline{1100}_2$. In Figure 9.3 the IEEE representations (with hidden bit technique) for different rounding modes are shown.
Special values named "not a number" (NaN) may be signaling or quiet (see Appendix B for the classification of `real` numbers and the IEEE exception handling).
Representations of some special values of the *real* data format are listed in Figure 9.4.

The order in which the bytes of a *real* value are stored depend on the storage conventions used by the hardware. This is most important in those cases where hardware support for arithmetic operations is used. Refer to the *local configuration guide* for details.
**Exercise** Give the binary representation of 1/7. What is its IEEE double representation? What is the relative error of $\square(1/7)$?

## 9.3 Module *x_real*

For the purpose of showing the bits of a real number in the order indicated by Figure 9.1 we can use the PASCAL-XSC standard module `x_real`.
Module `x_real` contains additional constants, types, functions, and procedures for an extended or alternative processing of *real* values. For the classification of *real* values we refer to Appendix B.

### 9.3.1 Composition and Decomposition of *real* Values

The default functions *comp*, *expo*, and *mant* assume an abstract representation of a non-zero normalized floating-point number with a normalized mantissa $m$ satisfying $B^{-1} \leq |m| < 1$. Here, $B$ stands for the base which is used for the representation of the digits of mantissa $m$.
In the special case $B = 2$, the abstract representation of a non-zero normalized floating-point number with a mantissa $m$ satisfying $1 \leq |m| < 2$ is possible, too. The binary IEEE data formats are defined by such a formulation. The functions `x_comp`, `x_expo` and `x_mant` handle *real* values according to this abstract representation.

```
function x_comp ( m : real; e : integer ) : real;
function x_expo ( r : real ) : integer;
function x_mant ( r : real ) : real;
```

### 9.3.2 Formatted Input/Output for *real* Values

The representation of *real* input and output values in a hexadecimal notation is made available by overloading the procedures *read* and *write* for *real* arguments.

```
procedure read ( var f : text; var r : real; mode : char );
procedure write( var f : text;     r : real; mode : char );
```

| Hexadecimal representation | Decimal value |
|---|---|
| FFF0000000000000 | $-\infty$ |
| FFEFFFFFFFFFFFFF | $-1.7976931348623158 \cdot 10^{308}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $-\infty$ yields $-\infty$. |
| BFF0000000000000 | $-1.0$ |
| 8010000000000000 | $-2.2250738585072013 \cdot 10^{-308}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $+\infty$ yields the smallest denormalized number. |
| 8000000000000001 | $-4.9406564584124654 \cdot 10^{-324}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $+\infty$ yields -0.0. |
| 8000000000000000 | $-0.0$ |
| 0000000000000000 | 0.0 |
| 0000000000000001<br>*minreal* | $4.9406564584124654 \cdot 10^{-324}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $-\infty$ yields 0.0. |
| 0010000000000000 | $2.2250738585072013 \cdot 10^{-308}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $-\infty$ yields the largest denormalized number. |
| 3FF0000000000000 | 1.0 |
| 7FEFFFFFFFFFFFFF<br>*maxreal* | $1.7976931348623158 \cdot 10^{308}$<br>Shortest decimal number which yields the specified hexadecimal value with rounding to the nearest floating-point value. Decimal to binary conversion of this number with rounding towards $+\infty$ yields $+\infty$. |
| 7FF0000000000000 | $+\infty$ |

Figure 9.4: Special *real* values

Both the input format and the output format is a fixed-format 16 digit hexadecimal notation. The left-most hexadecimal digit holds bit 63 through bit 60 of the floating-point number format as specified in Figure 9.1. The right-most hexadecimal digit holds bit 3 through bit 0.
Procedure `read` for hexadecimal input does not distinguish between lower case hexadecimal digits `a`, `b`, `c`, `d`, `e`, `f` and upper case hexadecimal digits `A`, `B`, `C`, `D`, `E`, `F`. Possible `mode` characters are '`x`' and '`X`'.
Procedure `write` may be called with `mode` character '`x`' or '`X`', which will produce lower case hexadecimal digits `a`, `b`, `c`, `d`, `e`, `f` or upper case hexadecimal digits `A`, `B`, `C`, `D`, `E`, `F`, respectively.
The PASCAL–XSC statement

```
writeln(1.0:'x',' = ',1.0:'X')
```

yields the following output line:

```
3ff0000000000000 = 3FF0000000000000
```

## 9.4 Measure of Errors

As usual we introduce for a nonzero number $x$ and its approximation $\tilde{x}$ the following two measures of error:

$$\varepsilon(\tilde{x}) := \frac{\tilde{x} - x}{x} \tag{9.1}$$

and

$$\Delta(\tilde{x}) := \tilde{x} - x \tag{9.2}$$

It holds

$$\tilde{x} = (1 + \varepsilon(\tilde{x})) \cdot x \tag{9.3}$$

The following relative error bound for the machine result $a \boxdot b$ is fulfilled by all four basic arithmetical operations $\circ \in \{+, -, \cdot, /\}$ whenever the corresponding exact result $a \circ b$ lies in the range of normalized numbers:

$$\left| \frac{a \circ b - a \boxdot b}{a \circ b} \right| < \varepsilon := 2^{-53} \tag{9.4}$$

Here $a, b$ denote normalized IEEE double numbers (see Figure 9.1). Notice, that for denormalized numbers this error bound is in general no longer valid. The so called machine epsilon (Wilkinson's epsilon) is defined by

$$\varepsilon := 0.5 \cdot B^{1-l} = 2^{-53} \in [1.11022E-16,\ 1.11023E-16] \tag{9.5}$$

where $l = 53$ is the number of digits with respect to the basis $B = 2$ of the IEEE double floating-point system.

# 9.5 Sine Function

We now consider the realization of mathematical functions. Let us first discuss a technique for bounding the sine for point arguments.

## 9.5.1 Sine Function for Point Arguments

We develop a very simple technique to get an enclosure of $\sin(x)$ for a point argument $x$. For the computation of $\sin(x)$ the reduction of the argument into the so called basic range (a small region with center zero) plays an important role.

### 9.5.1.1 Argument Reduction

For the given argument $x$ an argument reduction is performed into the range $[-\frac{\pi}{4}, \frac{\pi}{4}]$. The reduced argument $t$ can be computed by

$$\begin{array}{lcll} k & := & x \cdot \dfrac{2}{\pi} & \text{(real value)} \\ k & := & \text{round}(k) & \text{(integer value)} \\ t & := & x - k \cdot \dfrac{\pi}{2} & \in [-\frac{\pi}{4}, \frac{\pi}{4}] \end{array} \tag{9.6}$$

The reduction is illustrated in Figures 9.5 and 9.6. In Figure 9.6 segments plotted using the same line style are all mapped to their corresponding basic curve segment which crosses the y-axis.

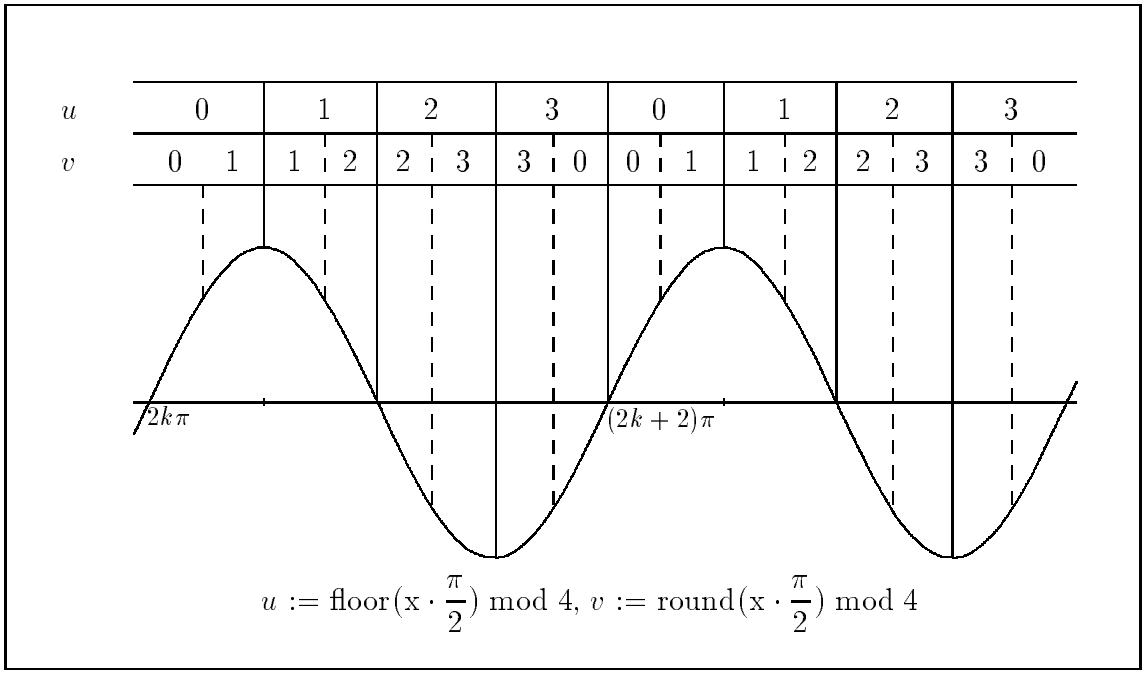

Figure 9.5: Reduction Process for the Sine Function

Using this reduction (it results in the two values $k$ and $t$) $\sin(x)$ can be computed according to

$$\sin(x) = \sin(t, k \bmod 4) \tag{9.7}$$

where the function $\sin(t, m)$ is defined by

$$\sin(t,m) := \begin{cases} \sin(t) & \text{if} \quad m = 0 \\ \cos(t) & \text{if} \quad m = 1 \\ -\sin(t) & \text{if} \quad m = 2 \\ -\cos(t) & \text{if} \quad m = 3 \end{cases} \tag{9.8}$$

Relation (9.8) is illustrated by Figure 9.6.

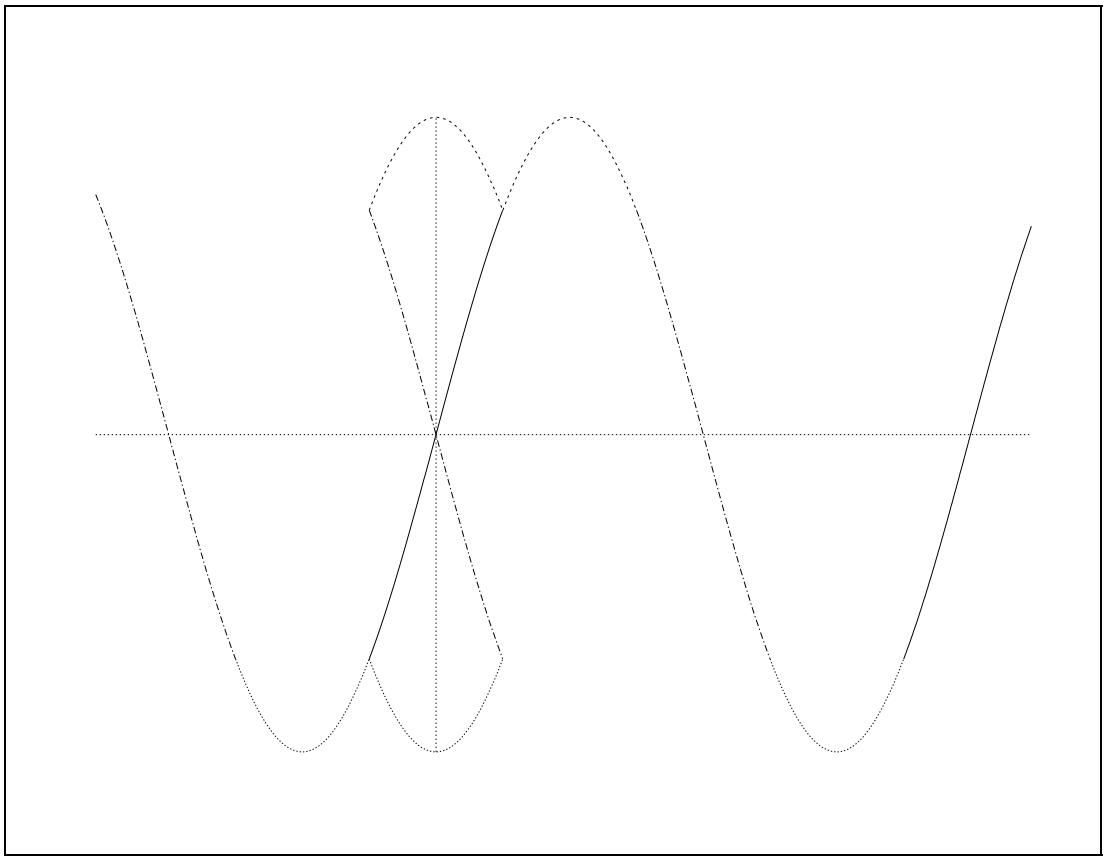

Figure 9.6: Reduction for the Sine to the Basic Range $[-\frac{\pi}{4}, \frac{\pi}{4}]$

#### 9.5.1.2 Approximation within the Basic Range

Now $\sin(t)$ and $\cos(t)$ for $t \in [-\frac{\pi}{4}, \frac{\pi}{4}]$ can be computed using their taylor expansions

$$\sin(t) = \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k+1)!} t^{2k+1} =: t \cdot p_\infty(t^2), \tag{9.9}$$

$$\cos(t) = \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k)!} t^{2k} =: q_\infty(t^2) \tag{9.10}$$

If we use the approximation $t \cdot p_n(t^2) := \sum_{k=0}^{n} \frac{(-1)^k}{(2k+1)!} t^{2k+1} \approx \sin(t)$ the approximation error is bounded by

$$\begin{aligned}
\left| \frac{\sin(t) - t \cdot p_n(t^2)}{\sin(t)} \right| &= \left| \frac{t \cdot \sum_{k=n+1}^{\infty} \frac{(-1)^k}{(2k+1)!} t^{2k}}{t \cdot \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k+1)!} t^{2k}} \right| \\
&\leq \frac{1}{1 - \frac{1}{6}t^2} \cdot \frac{t^{2n+2}}{(2n+3)!} \underbrace{\left| 1 - \underbrace{\frac{(2n+3)!}{(2n+5)!}}_{<1} t^2 + \underbrace{\frac{(2n+3)!}{(2n+7)!}}_{<1} t^4 - + \ldots \right|}_{\leq 1} \\
&\leq \frac{1}{1 - \frac{1}{6}t^2} \cdot \frac{t^{2n+2}}{(2n+3)!}
\end{aligned} \tag{9.11}$$

Thus, for $t \in [-\frac{\pi}{4}, \frac{\pi}{4}]$ the relative approximation error is bounded by

$$\left| \frac{\sin(t) - t \cdot p_n(t^2)}{\sin(t)} \right| \leq \frac{1}{1 - \frac{1}{6}\left(\frac{\pi}{4}\right)^2} \cdot \frac{\left(\frac{\pi}{4}\right)^{2n+2}}{(2n+3)!} =: \varepsilon(\sin, n). \tag{9.12}$$

For the approximation error of $q_n(t) := \sum_{k=0}^{n} \frac{(-1)^k}{(2k)!} t^{2k} \approx \cos(t)$ we find

$$\begin{aligned}
\left| \frac{\cos(t) - q_n(t^2)}{\cos(t)} \right| &\leq \left| \frac{\sum_{k=n+1}^{\infty} \frac{(-1)^k}{(2k)!} t^{2k}}{1 - \frac{1}{2}t^2} \right| \\
&\leq \frac{1}{1 - \frac{1}{2}t^2} \cdot \frac{t^{2n+2}}{(2n+2)!} \underbrace{\left| 1 - \frac{(2n+2)!}{(2n+4)!} t^2 + \frac{(2n+2)!}{(2n+6)!} t^4 - + \ldots \right|}_{<1} \\
&\leq \frac{1}{1 - \frac{1}{2}\left(\frac{\pi}{4}\right)^2} \cdot \frac{\left(\frac{\pi}{4}\right)^{2n+2}}{(2n+2)!} =: \varepsilon(\cos, n) \text{ for all } t \in [-\tfrac{\pi}{4}, \tfrac{\pi}{4}].
\end{aligned} \tag{9.13}$$

| $n$ | $\varepsilon(\sin, n)$ | $\varepsilon(\cos, n)$ |
|---|---|---|
| 5 | 9.8608205E-012 | 1.6630390E-010 |
| 6 | 2.8965000E-014 | 5.6365166E-013 |
| 7 | 6.5687749E-017 | 1.4487029E-015 |
| 8 | 1.1847809E-019 | 2.9203685E-018 |
| 9 | 1.7400772E-022 | 4.7406055E-021 |

Table 9.1: Errors for Sine and Cosine for Approximations with Different Degrees

Table 9.1 shows some values of $\varepsilon(\sin, n)$ and $\varepsilon(\cos, n)$ for different values of $n$. We can see that for the sine $n := 7$ and for cosine $n := 8$ lead to error bounds that are appropriate for the IEEE double format (64-bit, see Figure 9.1 and (9.5) ). The machine epsilon for this fomat is $\varepsilon = 2^{-53} = 1.110223\ldots 10^{-16}$.

To get an enclosure of $\sin(t)$, $t \in [-\frac{\pi}{4}, \frac{\pi}{4}]$ we proceed as follows. Let $a_k := \dfrac{(-1)^k}{(2k+1)!}$, $b_k := \dfrac{(-1)^k}{(2k)!}, k = 0, \ldots, n$ denote the polynomial coefficients of $p_n(t) \approx \sin(t)$ and $q_n(t) \approx \cos(t)$ and $[a_k]$ and $[b_k]$ be intervals with $a_k \in [a_k], b_k \in [b_k], k = 0, 1, \ldots, n$. Using the inclusion monotonicity of interval arithmetic we get with $[tt] := t \diamondsuit t \in I\!I\!R$

$$\begin{aligned} t \cdot p_n(t^2) \quad \in \quad & t \diamondsuit (\ldots (([a]_n \diamondsuit [tt] \oplus [a]_{n-1}) \diamondsuit [tt] \oplus [a]_{n-2}) \\ & \diamondsuit [tt] \oplus \ldots) \oplus [tt] \oplus [a]_0 =: [t \cdot p_n(t^2)] \end{aligned} \tag{9.14}$$

and using the error bound $\varepsilon(\sin, n) =: \varepsilon(\sin)$,

$$\sin(t) \in [t \cdot p_n(t^2)] \diamondsuit [1 - \varepsilon(\sin), 1 + \varepsilon(\sin)] =: [s(t)].$$

Similarly one finds

$$\cos(t) \in [q_n(t^2)] \diamondsuit [1 - \varepsilon(\cos), 1 + \varepsilon(\cos)] =: [c(t)]\,. \tag{9.15}$$

Here $[q_n(t^2)]$ denotes the interval Horner scheme corresponding to the polynomial $q_n(t^2)$ and $\varepsilon(\cos) := \varepsilon(\cos, n)$. Up to now we are able to compute enclosures of $\sin(t)$ and $\cos(t)$ for point arguments lying in the range $[-\frac{\pi}{4}, \frac{\pi}{4}]$ (reduced argument range). The interval functions $[s(t)]$ and $[c(t)]$ can be combined to get an interval analogon $\mathrm{Sin}([t], m)$ to $\sin(t, m)$ as defined in (9.8):

$$\mathrm{Sin}([t], m) := \begin{cases} [s([t])] & \text{if} \quad m = 0 \\ [c([t])] & \text{if} \quad m = 1 \\ -[s([t])] & \text{if} \quad m = 2 \\ -[c([t])] & \text{if} \quad m = 3 \end{cases} \tag{9.16}$$

Here $[t]$ denotes an interval wich contains the reduced argument $t$, i.e. $[t]$ may be the result of an argument reduction according to (9.6), which is performed in interval

arithmetic:

$$\begin{aligned} k &:= x \boxdot \left.\frac{2}{\pi}\right|_{\mathrm{IEEE}} \\ k &:= \mathrm{round}(k) \qquad . \\ [t] &:= x \diamondsuit k \diamondsuit \left[\frac{\pi}{2}\right] \in I\!I\!R \end{aligned} \tag{9.17}$$

The quantity $\left.\frac{2}{\pi}\right|_{\mathrm{IEEE}}$ is the IEEE double floating-point number nearest to the real value $2/\pi$ and $\left[\frac{\pi}{2}\right]$ denotes the smallest intervall with IEEE double bounds which contains $\pi/2$. Then, using relations (9.17) and (9.7), we find the enclosure

$$\sin(x) = \sin(t,\ k \bmod 4) \in \mathrm{Sin}([t], k \bmod 4) \in I\!I\!R\,. \tag{9.18}$$

### 9.5.2 Sine Function for Interval Arguments

In the previous paragraph we have developed an algorithm to compute an enclosure of $\sin(x)$ for an arbitrary point argument $x \in I\!R$. Let us now discuss the intervall case. Again we are interested in a simple method, which avoids a priori error estimations.
To compute an enclosure of $\sin([\,\underline{x}, \overline{x}\,])$ we proceed as follows:

1. reduce the point argument $\underline{x}$ to get $[\,\underline{t}\,]$ and $\underline{k}$ according to (9.17).

2. reduce $\overline{x}$ to get $[\,\overline{t}\,]$ and $\overline{k}$ according to (9.17).

3. set the boolean values $r_{lb}$, $r_{ub}$ as follows:

$$r_{lb} := [x] \cap \{\ldots, -\frac{5}{2}\pi, -\frac{1}{2}\pi, \frac{3}{2}\pi, \frac{7}{2}\pi, \frac{11}{2}\pi, \ldots\} = \emptyset$$

$$r_{ub} := [x] \cap \{\ldots, -\frac{3}{2}\pi, \frac{1}{2}\pi, \frac{5}{2}\pi, \frac{9}{2}\pi, \ldots\} = \emptyset$$

   i.e. $r_{lb}$ is true, if the interval $[x] = [\,\underline{x}, \overline{x}\,]$ under consideration contains a real number, say $y$, with $\sin(y) = -1$ and $r_{ub}$ is true, if $[x]$ contains a value $z$, with $\sin(z) = 1$.

4. $[u] := \mathrm{iSin}([\,\underline{t}\,], \underline{k} \bmod 4) \quad (\ni \sin(\underline{x}))$

   $[v] := \mathrm{iSin}([\,\overline{t}\,], \overline{k} \bmod 4) \quad (\ni \sin(\overline{x}))$

5. **if** $r_{lb}$ **then**
   $\underline{r} := -1$
   **else**
   $\underline{r} := \min\{\inf[u], \inf[v]\}$
   **if** $r_{ub}$ **then**
   $\overline{r} := 1$
   **else**
   $\overline{r} := \max\{\sup[u], \sup[v]\}$

Now it holds

$$\sin([\,\underline{x}, \overline{x}\,]) \subseteq [\,\underline{r}, \overline{r}\,]$$

#### 9.5.2.1 Algorithms

The argument reduction for the sine is done according to

**Algorithm 9.1:** ArgRed $(x, [t], k)$ {subroutine}

1. $k := \text{round}\left(x \boxdot \left.\frac{2}{\pi}\right|_{\text{IEEE}}\right)$ { floating point computation }
2. $[t] := x \diamondminus k \diamondsuit \left[\frac{\pi}{2}\right]$ { reduced argument }
3. **return** $[t], k$

Compute an enclosure of $\sin(t)$ with $t$ lying in the basic range as follows:

**Algorithm 9.2:** Sin $([t])$ {function}

1. $[a_k] := \left[\frac{(-1)^k}{(2k+1)!}\right],\ k = 0, 1, \ldots, n := 7,\ \varepsilon(\sin) := \varepsilon(\sin, n)$ (see Table 9.1)
2. $[tt] := [t][t]$
3. $[s] := [a_n]$ {Interval Horner's scheme}
   **for** $j := n - 1$ **downto** $0$ **do**
   $[s] := [s][tt] + [a_j]$
4. $[s] := [t][s][1 - \varepsilon(\sin), 1 + \varepsilon(\sin)]$ {Take into account the approximation error}
5. **return** Sin $:= [s]$

Now we list the corresponding algorithm for enclosing $\cos(t)$ with $t$ in the basic interval:

## Algorithm 9.3: Cos $([t])$ {function}

1. $[b_k] := [\frac{(-1)^k}{(2k)!}], k = 0, 1, \ldots, n := 8, \quad \varepsilon(\cos) := \varepsilon(\cos, n)$ (see Table 9.1)
2. $[tt] := [t][t]$
3. $[s] := [b_n]$
   **for** $j := n - 1$ **downto** $0$ **do**
   $[s] := [s][tt] + [b_j]$
4. $[s] := [s][1 - \varepsilon(\cos), 1 + \varepsilon(\cos)]$ {Take into account the approximation error}
5. **return** Cos $:= [s]$

## Algorithm 9.4: Sin $([t], m)$ {function}

1. **if** $m = 0$ **then**
   $[s] :=$ Sin $([t])$
   **else if** $m = 1$ **then**
   $[s] :=$ Cos $([t])$
   **else if** $m = 2$ **then**
   $[s] := -$Sin $[t]$
   **else**
   $[s] := -$Cos $[t]$
2. **return** Sin $:= [s]$

If we only want to enclose function values for point arguments, we can use

## Algorithm 9.5: SinSimp $(x)$ {function}

1. Compute $[t]$ and $k$ by ArgRed $(x, [t], k)$
2. $[s] :=$ Sin $([t], k \bmod 4)$
3. **return** SinSimp $:= [s]$

An enclosure of $\sin[x]$ for an interval argument $[x]$ is computed by

## Algorithm 9.6: SinSimp $([x])$ {function}

1. Compute $[\,\underline{t}\,], \underline{k}$ by ArgRed $(\underline{x}, [\,\underline{t}\,], \underline{k})$
2. Compute $[\,\overline{t}\,], \overline{k}$ by ArgRed $(\overline{x}, [\,\overline{t}\,], \overline{k})$
3. $r_{Ik} := [x] \cap \{\frac{3}{2}\pi \pm j2\pi | j = 0, 1, 2 \ldots\} = \emptyset$

4. $r_{ub} := [x] \cap \{\frac{1}{2}\pi \pm j2\pi | j = 0, 1, 2, \ldots\} = \emptyset$
5. $[u] :=$ Sin $([\,\underline{t}\,], \underline{k} \bmod 4)$
   $[v] :=$ Sin $([\,\overline{t}\,], \overline{k} \bmod 4)$
6. **if** $r_{lb}$ **then** $\underline{r} := -1$
   **else** $\underline{r} := \min\{\inf[u], \inf[v]\}$
7. **if** $r_{ub}$ **then** $\overline{r} := 1$
   **else** $\overline{r} := \max\{\sup[u], \sup[v]\}$
8. **return** SinSimp $:= [\,\underline{r}, \overline{r}\,]$

#### 9.5.2.2 Program Code

The module `sinm` supplies all functions and subroutines as introduced in the last paragraph. Only the routine SinSimp is defined as a global function. It allows to compute the range of the sine over an interval $[x]$. We do not redefine the PASCAL-XSC intrinsic function `sin`. So our test routines can use the new algorithm as well as the intrinsic PASCAL-XSC version. The implementation given here is far away from being optimal. If one uses a priori error estimations including all possible rounding errors and errors introduced by the conversion of real constants into the floating point screen the algorithm will run at least as twice as fast. The efficiency can be even more increased even more using best approximations for sine and cosine within the basic interval $[-\frac{\pi}{4}, \frac{\pi}{4}]$. The numerical quality can also be increased significantly. See the remarks following our numerical examples.
We now list the program code according to the algorithms given in the last paragraph.

### 9.5.2.3 Numerical Examples

A simple driver program is shown now:

```
PROGRAM sinmtst;   { Driver for module sinm }

USE i_ari; { Interval operations }
USE sinm;  { Make the new interval function SinSimp available }

VAR x, iSinx, sinx: interval;
    k: integer;
BEGIN
   { Compare the intrinsic sin and iSin for some powers of two }
   FOR k := -2 TO 10 DO BEGIN
      x:= power(2.0, 3*k);    { x = 2**(3k) }
      iSinx:= SinSimp(x);  { Simple version of the sine    }
      sinx := sin(x);      { PASCAL-XSC intrinsic function }
      writeln('SinSimp(2**', 3*k:2, '): ', iSinx);
      IF NOT(sinx <= iSinx) THEN writeln('*** A t t e n t i o n  !!!');
   END;
   writeln('sin(2**30) using the intrinsic sin of PASCAL-XSC:');
   writeln('   sin: ', sinx);
   writeln('sin(2**30) using the new function SinSimp:');
   writeln('  iSin: ', iSinx);
END.
```

Running the driver program `sinmtst` produces the following output:

```
SinSimp(2**-6): [   1.56243642248833E-002,   1.56243642248834E-002 ]
SinSimp(2**-3): [   1.24674733385227E-001,   1.24674733385228E-001 ]
SinSimp(2** 0): [   8.41470984807895E-001,   8.41470984807898E-001 ]
SinSimp(2** 3): [   9.89358246623380E-001,   9.89358246623384E-001 ]
SinSimp(2** 6): [    9.2002603819678E-001,    9.2002603819680E-001 ]
SinSimp(2** 9): [      7.95184940128E-002,      7.95184940130E-002 ]
SinSimp(2**12): [     -5.94641987609E-001,     -5.94641987607E-001 ]
SinSimp(2**15): [      9.27856333412E-001,      9.27856333416E-001 ]
SinSimp(2**18): [       -8.410702783E-002,       -8.410702776E-002 ]

SinSimp(2**24): [        -7.79563676E-001,        -7.79563671E-001 ]
SinSimp(2**27): [         -7.6340325E-001,         -7.6340322E-001 ]
SinSimp(2**30): [          -6.173267E-001,          -6.173261E-001 ]
sin(2**30) using the intrinsic sin of PASCAL-XSC:
```

```
    sin: [ -6.173264150460423E-001, -6.173264150460421E-001 ]
sin(2**30) using the new function SinSimp:
   iSin: [          -6.173267E-001,          -6.173261E-001 ]
```

For larger arguments (all data are point intervals) the enclosures are no longer satisfactorily. The great width of the enclosures is due to the inaccurate argument reduction.

## 9.5.3 Improved Version for $\sin([x])$

### 9.5.3.1 Accurate Argument Reduction

The realization of the argument reduction

$$k := \text{round}(x \cdot \frac{2}{\pi})$$

$$t := x - k \cdot \frac{\pi}{2}$$

by naive interval arithmetic (see (9.17)) leads for arguments $x$ near to a multiple of $\pi/2$ or for $|x|$ large to a significant loss of accuracy. The relative error may be very large. This loss of accuracy can be easily avoided using the accurate dot product of PASCAL-XSC:
Let the constants $c_j, j = 1, 2, \ldots, j_{\max}$ be defined by

$$c_1 := \bigtriangledown(\frac{\pi}{2}) \tag{9.19}$$

$$c_k := \bigtriangledown(\frac{\pi}{2} - \sum_{j=1}^{k-1} c_j),\ k = 2, \ldots, j_{\max} - 1 \tag{9.20}$$

$$[c_{j_{\max}}] := \diamondsuit(\frac{\pi}{2} - \sum_{j=1}^{j_{\max}-1} c_j). \tag{9.21}$$

The sum of the $c_j$ is a very good approximation (about $j_{\max} \cdot 53$ bits are correct) for $\frac{\pi}{2}$ and it holds $\frac{\pi}{2} \in \sum_{j=1}^{j_{\max}-1} c + [c]_{j_{\max}}$.
Using these values, we make the following reduction

$$k := \text{round}(\square(x \boxdot \square(\frac{2}{\pi}))) \tag{9.22}$$

$$[t] := \diamondsuit(\, x - k \sum_{j=1}^{j_{\max}-1} c_j - k \cdot [c_{j_{\max}}]\,) \tag{9.23}$$

The formula for $[t]$ is computed as an interval scalar product. So the exact result of the expression is rounded outward only once. The number $j_{\max}$ of constants $c_j$

has to be chosen appropriately. We will not do this by an a priori error estimation. Heuristically we will expect a cancellation of 53 bits for arguments very close to a small multiple of $\pi/2$ and for arguments with large absolut value ($\approx$ maxint $\cdot$ $\pi/2 \approx (2^{31}-1)\cdot 1.57 \approx 3.37E9$) additionally 30 bits may suffer by cancellation. An approximation to $\pi/2$ by the sum of 3 IEEE numbers should produce reduced arguments to almost full accuracy. Maybe, that in rare cases this does not hold. Nevertheless, in any case, it is correct, that the computed interval $[t]$ contains the value of the reduced argument $t$, $t$ computed in the field of the real numbers. The inclusion property $\sin[x] \subseteq \sin_{\diamondsuit}([x])$ will not be corrupted. The notation $\sin_{\diamondsuit}([x])$ means the result as it is computed on the computer.

#### 9.5.3.2 Improved Interval Logic for the Sine Function

In many cases it is possible to compute an enclosure of $\sin[x]$ using only one function evaluation $\sin_{\diamondsuit}([t])$. We only have to supplement the argument reduction step appropriately. The additional information can be used, to construct $[\underline{r}, \overline{r}] \supseteq \sin[x]$ in an efficient manner.
The reduction step gives back not only the value $k$, which is computed by

$$u := x \boxdot \frac{2}{\pi}\Big|_{\text{IEEE}} \tag{9.24}$$

$$k := \text{round}(u) \tag{9.25}$$

but also the integer value

$$\text{q} := \text{ greatest integer less than or equal to } \frac{2}{\pi}\Big|_{\text{IEEE}} . \tag{9.26}$$

The quantity $1 + (\text{q mod } 4)$ indicates the position of the original argument $x$ (interpreted as an angle given in radians) in the plane. Here all angles $u + 2k\pi,\ 0 \le u < 2\pi$ lead to the same value of q.
To find an enclosure of $\sin[x]$ we proceed as follows:

1. **if** $\text{diam}[x] \ge 2\pi$ **then return** $r := [-1, 1]$
2. reduce the point argument $\underline{x}$ to get $[\,\underline{t}\,], \underline{k}$ and $\underline{q}$ according to (9.23), (9.24), (9.25) and (9.26)
3. reduce $\overline{x}$ to get $[\,\overline{t}\,], \overline{k}, \overline{q}$ according to (9.23), (9.24), (9.25) and (9.26)
4. use $\underline{k}, \underline{q}$ and $\overline{k}, \overline{q}$ to find the appropriate case according to Figure 9.7 , i. e. find $m$ and $M$ according to Figure 9.7
5. **return**

$$\underline{r} := \sin(m) \text{ and } \overline{r} := \sin(M)$$

Now $\sin([x]) \subseteq [\underline{r}, \overline{r}]$.

Step 4. has to be explained in more detail. Figure 9.7 shows all relavant cases of different positions of $[x]$. Other cases lead to the result $[r] = [-1, 1]$ because $\mathrm{diam}[x] \geq 2\pi$ or they can be reduced to one of the indicated positions by adding a suitable multiple of $2\pi$ to $[x]$. Because the sine is a periodic function with period $2\pi$ this does not alter the resulting interval.
The argument $[x]$ is shown as a line segment parallel to the x-axes. The positions where sin takes on its maximum or its minimum in $[x]$ are indicated by $m$ or $M$, respectively. That means $r = [\underline{r}, \overline{r}] = [\sin(m), \sin(M)] = \sin[x]$. If $m$ is an interior point of $[x]$, i.e. $\underline{x} < m < \overline{x}$, then $\sin(m)$ must not be calculated. In this case $\sin(m) = -1$. Similarly, if $\underline{x} < M < \overline{x}$, then $\sin(M) = +1$. Again, no function call is necessary. Figure 9.7 shows, that in many cases only one function call suffices to find $[r] = \sin[x]$.
In the PASCAL-XSC program given below the cases indicated by $(^*)$ are not handled separately. In both cases the minimum is computed as $\underline{r} = \min\{\sin \underline{x}, \sin \overline{x}\}$. Similarly, in the cases indicated by $(^{**})$ $\overline{r} = \max\{\sin \underline{x}, \sin \overline{x}\}$.

#### 9.5.3.3 Algorithmic Description of the Improved Version

The first algorithm summarizes the accurate argument reduction. The second algorithm shows the improved 'interval logic'.

## Algorithm 9.7: ArgRed $(x, [t], k, q)$ {subroutine}

1. $u := x \boxdot \left.\frac{\pi}{2}\right|_{\mathrm{IEEE}}$ {floating-point number}
2. $k := \mathrm{round}(u)$ {integer}
3. $q := \mathrm{floor}(u)$ {integer}
4. $[t] := \diamondsuit(x - \sum_{j=1}^{jMax} kc_j - k[c_{jMax}])$ {interval scalar product results in an interval}
5. **return** $[t], k, q$

## Algorithm 9.8: iSin { }

**if** $\mathrm{diam}[x] = 0$ **then**

ArgRed $(\underline{x}, [\,\underline{t}\,], \underline{q}, \underline{k})$

$[s] := \sin([\,\underline{t}\,], \underline{k} \bmod 4)$

**else if** $\mathrm{diam}[x] \geq 2\pi$ **then** $[s] := [-1, 1]$

**else**

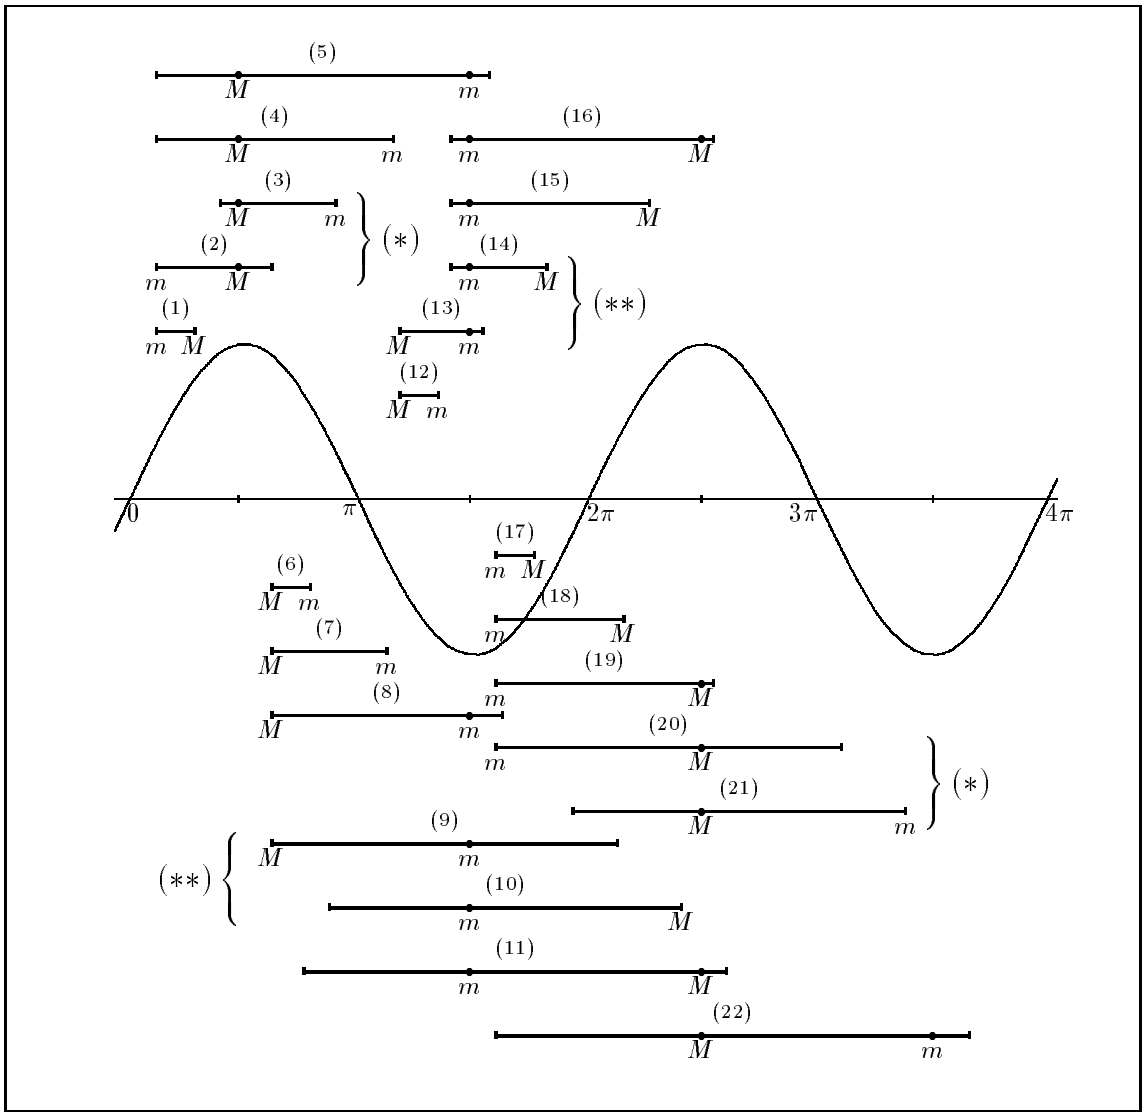

Figure 9.7: Sine Function – Interval Logic

ArgRed $(\underline{x}, [\,\underline{t}\,], \underline{q}, \underline{k})$

ArgRed $(\overline{x}, [\,\overline{t}\,], \overline{q}, \overline{k})$

**if** $\underline{q} = \overline{q}$ **then**

  **if** $\mathrm{diam}[x] \geq \pi$ **then** $[s] := [-1, 1]$

  **else** $[s] := \sin([\,\underline{t}\,], \underline{k}) \underline{\cup} \sin([\,\overline{t}\,], \overline{k})$

**else**

  **if** $\underline{q} = 0$ **then**

    **if** $\overline{q} = 1$ **then** $[s] := [\min\{\sin([\underline{t}], \underline{k}), \sin([\overline{t}], \overline{k})\}, 1]$

    **else if** $\overline{q} = 2$ **then** $[s] := [\sin([\overline{t}], \overline{k}), 1]$

    **else** $[s] := [-1, 1]$

**else if** $\underline{q} = 1$ **then**
  **if** $\overline{q} = 0$ **then** $[s] := [-1, \max\{\sin([\underline{t}], \underline{k}), \sin([\overline{t}], \overline{k})\}]$
  **else if** $\overline{q} = 2$ **then** $[s] := \sin([\,\underline{t}\,], \underline{k}) \underline{\cup} \sin([\,\overline{t}\,], \overline{k})$
  **else** $[s] := -1 \underline{\cup} \sin([\,\overline{t}\,], \overline{k})$
**else if** $\underline{q} = 2$ **then**
  **if** $\overline{q} = 0$ **then** $[s] := -1 \underline{\cup} \sin([\overline{t}], \overline{k})$
  **else if** $\overline{q} = 1$ **then** $[s] := [-1, 1]$
  **else** $[s] := [-1, \max\{\sin([\underline{t}], \underline{k}), \sin([\overline{t}], \overline{k})\}]$
**else if** $\underline{q} = 3$ **then**
  **if** $\overline{q} = 0$ **then** $[s] := \sin([\underline{t}], \underline{k}) \underline{\cup} \sin([\overline{t}], \overline{k})$
  **else if** $\overline{q} = 1$ **then** $[s] := \sin([\underline{t}], \underline{k}) \underline{\cup} 1$
  **else** $[s] := [\min\{\sin([\underline{t}], \underline{k}), \sin([\overline{t}], \overline{k})\}, 1]$

1. **return** iSin $:= [s]$

Here the minimum (maximum) of two intervals means the minimum (maximum) of the two lower (upper) bounds of these intervals. The symbol $\underline{\cup}$ denotes the interval hull of its two arguments.

#### 9.5.3.4 Program Code

We now give the PASCAL-XSC code of the module `sinmi` containing the improved implementation `iSin`.

```

### 9.5.3.5 Numerical Examples using the Improved Sine Routine

The following program `sinmitst` computes enclosures for sin([r,r]), r varying in the neighbourhood of $10000 \cdot \pi$. The intrinsic PASCAL-XSC function `pred` computes the predecessor and the function `succ` the successor of a floating-point number.

```
{-------------------------------------------------------------------}
{ Driver for the module sinmi (Improved Version of Sine)            }
{-------------------------------------------------------------------}
PROGRAM sinmitst;

USE i_ari;    { Interval operations                                 }
USE sinmi;    { Module with improved version for interval sine }
USE fnc_util; { Make available functions NextAfter, Max, ...   }

VAR
   i, factor: integer;
   x, r: real;
BEGIN
   factor:= 10000;
   x:=4*arctan(1.0);                     { approximation to pi }
   x:= factor*x;
   writeln(
     'Check the accuracy of the improved version iSin(x) around ',
      factor:0, '*Pi:');
   r:= NextAfter(x, -5); { go left 5 flp-numbers }
   FOR i:= 1 TO 10 DO BEGIN
     r:= succ(r);
     writeln( iSin(intval(r,r)) );
   END;
   r:= power(2,30);
   writeln; writeln('Compute iSin(2**30) = iSin(', r:12:1, '):');
   writeln( iSin(intval(r,r)) );
END.
{-------------------------------------------------------------------}
```

The output of the driver program is as follows:

```
Check the accuracy of the improved version iSin(x) around 10000*Pi:
[  -1.50375975823238E-011,  -1.50375975823236E-011 ]

```

Compare the width of the computed enclosure of $\sin(2^{30})$ with the width of the enclosure as it was computed in Subsection 9.5.2.3 using the more simple algorithm `SinSimp`.

## 9.6 Exponential Function

In this section we start with a simple method to compute enclosures for $\exp(x)$. An improved version using an a priori error estimation will be discussed in Subsection 9.6.2.2.

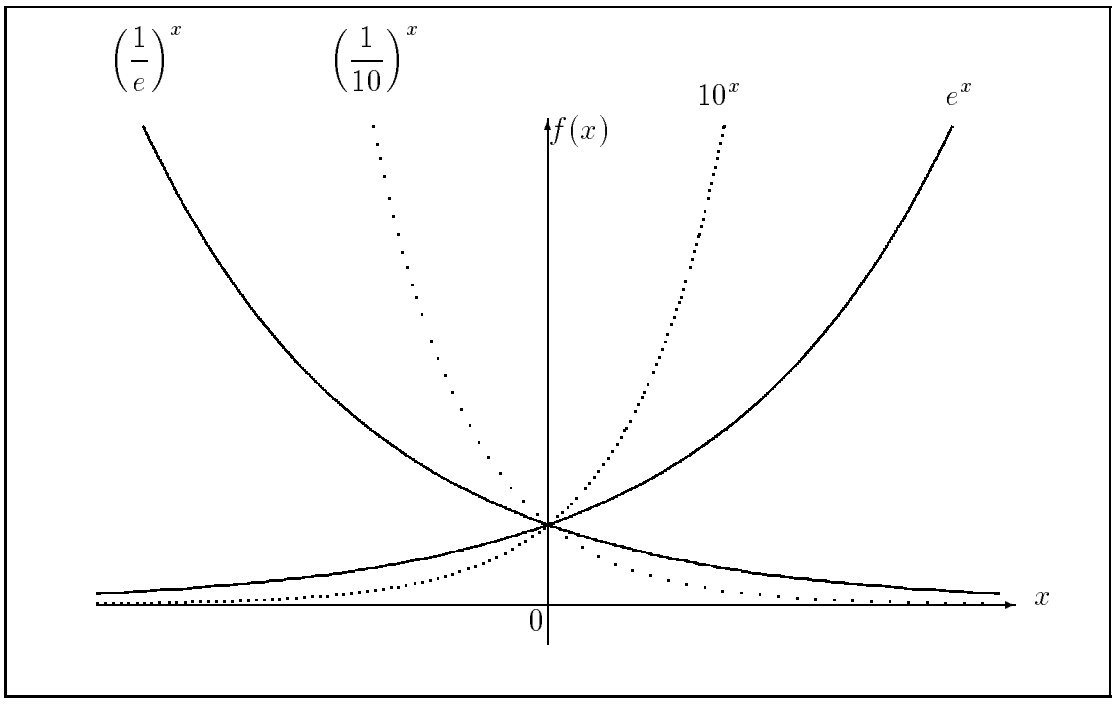

Figure 9.8: Exponential Function

### 9.6.1 Exponential Function for Point Arguments

The computation of the exponential $\exp(x) = e^x$ is done in three steps:

1. argument reduction into a basic interval
2. approximation within the basic interval
3. result adaptation.

#### 9.6.1.1 Argument Reduction

Because

$$\exp(x) = \begin{cases} \exp(|x|) & , \quad x \geq 0 \\ \dfrac{1}{\exp(|x|)} & , \quad x < 0 \end{cases} \tag{9.27}$$

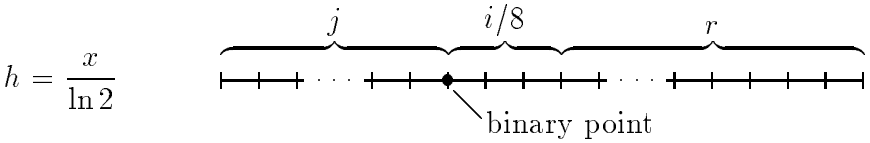
we restrict the range reduction without loss of generality to positive arguments $x \geq 0$.
Then we may write

$$e^x = 2^{\log_2 e^x} = 2^{x \cdot \log_2 e} = 2^{x \cdot \frac{1}{\ln 2}} =: 2^{j + i/8 + r} \tag{9.28}$$

with $j$ integer, $i \in \{0, 1, \ldots, 7\}$, and $0 \leq r < \dfrac{1}{8}$.
The value

$$e^x = 2^{j + i/8 + r} = 2^j \cdot 2^{i/8} \cdot 2^r \tag{9.29}$$

may be computed by an approximation to $2^r$, $0 \leq r < 1/8$, one additional multiplication by the prestored constant $2^{i/8}$ and by adding $j$ to the exponent of the resulting product.
The value $j$ is nothing else but the integral part of $h := x/\ln 2$ and $i$ is given by the bit combination of the first three bits behind the binary point of $h$.



Range Reduction: Splitting of $h$ in three parts

The quantities $j$, $i$ and $r$ are computed as follows:

$$\left.\begin{array}{lcll} h & := & x \cdot \dfrac{1}{\ln 2} & \\ j & := & \mathrm{trunc}(h) & \\ h & := & h - j & \\ i & := & \mathrm{trunc}(8 \cdot h) & \in \{0, 1, \ldots, 7\} \\ r & := & h - \dfrac{i}{8} & \end{array}\right\} \tag{9.30}$$

Thus $\dfrac{x}{\ln 2} = j + \dfrac{i}{8} + r$ with $r \in [0, \dfrac{1}{8})$.

#### 9.6.1.2 Approximation Within the Basic Interval

We are interested in the value of $2^r$ for arguments $r \in [0, \frac{1}{8})$.

$$2^r = e^{r \cdot \ln 2} = \sum_{k=0}^{\infty} \frac{(\ln 2)^k}{k!} r^k = \sum_{k=0}^{\infty} q_k r^k \tag{9.31}$$

with coefficients

$$q_k := \frac{(\ln 2)^k}{k!}. \tag{9.32}$$

Truncating this series after $n+1$ summands leads to the relative approximation error

$$\begin{aligned} \left| \frac{2^r - \sum_{k=0}^{n} q_k r^k}{2^r} \right| &= \left| \frac{\sum_{k=n+1}^{\infty} q_k r^k}{2^r} \right| \\ &\leq q_{n+1} r^{n+1} \sum_{k=n+1}^{\infty} \underbrace{\frac{q_k}{q_{n+1}}}_{\in [0,1]} r^{k-(n+1)} \\ &\underset{(0 \leq r < 1/8)}{\leq} q_{n+1} r^{n+1} \cdot \frac{1}{1-r} \end{aligned} \tag{9.33}$$

Using $n = 9$ we find as an upper bound for the relative approximation error

$$q_{10} r^{10} \frac{1}{1-r} \underset{(0 \leq r < 1/8)}{\leq} \frac{(\ln 2)^{10}}{10!} \left(\frac{1}{8}\right)^{10} \underbrace{\frac{1}{1 - \frac{1}{8}}}_{< 1.15} < 7.6 \cdot 10^{-18}. \tag{9.34}$$

So the approximation

$$p_9(r) := \sum_{k=0}^{10} \frac{(\ln 2)^k}{k!} r^k \approx 2^r, \qquad r \in [0, \frac{1}{8}] \tag{9.35}$$

is appropriate for the IEEE 64 bit floating-point screen (see (9.5)) .

#### 9.6.1.3 Result Adaptation

As result adaptation we have to compute

$$e^x = 2^{\frac{\ln 2}{x}} = 2^j \cdot 2^{i/8} \cdot 2^r, \tag{9.36}$$

$j$, $i$ and $r$ according to (9.30). The integer $i$ ranges from 0 to 7. Therefore we must know the constants

$$c_i := 2^{i/8} = \sqrt[8]{2^i}, \quad i = 0, 1, \ldots, 7. \tag{9.37}$$

These quantities are stored as precomputed IEEE floating-point numbers in a small table. In order to get an enclosure of the function value $\exp(x)$ actually the constants are enclosed by floating-point intervals.

#### 9.6.1.4 Algorithms

The Argument reduction for $\exp(x)$ is done by

**Algorithm 9.9:** ArgRed $(x, [r], j, i)$ {subroutine}

1. $[h] := x \cdot \diamondsuit(\frac{1}{\ln 2})$ $\quad \{[h] = [\underline{h}, \overline{h}]\}$
2. $j := \text{trunc}(\underline{h})$
3. $[h] := [h] - j$
4. $i := \text{trunc}(8 \cdot \underline{h})$
5. $[h] := [h] - i/8$
6. **return** $[r] := [h], j, i$

The approximation within the basic range is as follows:

**Algorithm 9.10:** Approx $([r])$ {function}

{It is assumed $[q_k] \ni \dfrac{(\ln 2)^k}{k!} = q_k, \quad k = 0, 1, \ldots, n$}

$[s] := [q_n]$

**for** $k := n - 1$ **downto** $0$ **do**

$\quad [s] := [s] \cdot [r] + [q_k]$

$[s] := [s] \cdot [1 - \varepsilon, 1 + \varepsilon]$ $\quad$ {$\varepsilon$ bounds the approximation error}
{it holds $2^{[r]} \subseteq [s]$}

**return** Approx $:= [s]$

An enclosure for $\exp(x)$ for a point argument x may be computed by

**Algorithm 9.11:** ExpSimp $(x)$ {function}

{It is assumed: $2^{i/8} \in [c_i], i = 0, 1, \ldots, 7$}

**if** $x > MaxExpArg$ **then**

*ERROR*

**else if** $x = 0$ **then** $[s] := 1$

**else if** $x < MinArg$ **then** $[s] := [0, succ(0.0)]$

**else**

$neg := (x < 0)$

ArgRed $(abs, [r], j, i)$

$[s] :=$ Approx $([r])$ {it holds $2^{[r]} \subseteq [s]$ }

$[s] := 2^j \cdot [s] \cdot [c_i]$ {it holds $e^{|x|} \in [s]$ }

**if** $neg$ **then** $[s] := 1/[s]$

{now it holds $e^x \in [s]$ }

**return** ExpSimp $:= [s]$

#### 9.6.1.5 Program Code

In the following PASCAL-XSC module `expm` Algorithm 9.10 (Approx $([r])$) is not implemented as a separate function. Instead, it is included in the main routine ExpSimp . We now give the PASCAL-XSC source code for the module `expm`. Here the simple program version `ExpSimp` which computes an interval enclosure of $\exp(x)$ is implemented.

```

    expm;   { Exponential module simple version }

VAR
  k  : integer;  { Loop variable                                  }
  arg: integer;  { For better readability we use integer arguments }
  res: interval; { Enclosure for exp(arg)                         }
BEGIN
  arg:= -50;
  FOR k:= 1 TO 6 DO BEGIN
     arg:= arg + 50;
     res:= ExpSimp(arg);
     writeln('ExpSimp(', arg:3, ')=', res);
  END;
  writeln('Use the intrinsic PASCAL-XSC exp routine:');
  res:= exp(arg);
  writeln('exp(    ', arg:3, ')=', res);
END.
```

This program **expmtst** produces the following output:

```
ExpSimp(  0)=[  1.000000000000000E+000,  1.000000000000000E+000 ]
ExpSimp( 50)=[    5.1847055285870E+021,    5.1847055285872E+021 ]
ExpSimp(100)=[    2.6881171418161E+043,    2.6881171418163E+043 ]
ExpSimp(150)=[    1.3937095806663E+065,    1.3937095806665E+065 ]
ExpSimp(200)=[     7.225973768125E+086,     7.225973768127E+086 ]
ExpSimp(250)=[     3.746454614502E+108,     3.746454614503E+108 ]
Use the intrinsic PASCAL-XSC exp routine:
exp(    250)=[  3.746454614502673E+108,  3.746454614502674E+108 ]
```

For larger arguments the enclosures become worse. This is due to cancellation effects when reducing the argument.

## 9.6.2 Improved Version of the Exponential

We now discuss a version for the computation of the exponential which exploits a priory error estimations and which performs an accurate range reduction.

### 9.6.2.1 Accurate Range Reduction

In 9.6.1.1 we have already discussed the range reduction for the exponential. The critical point is the cancellation of leading bits when substracting the integral part $j$ and the first three bits (given by the value $i/8$) after the binary point of $x/\ln 2$ from $x/\ln 2$. On the machine the value $x/\ln 2$ is computed by $x \boxtimes \left.\frac{1}{\ln 2}\right|_{\mathrm{IEEE}}$. Because $1/\ln 2$ is an irrational number it cannot be stored as a floating-point number with finite precision. Thus the leading product in the formula

$$r = x \cdot \frac{1}{\ln 2} - j - i$$

for the reduced argument $r$ is in general not exactly representable. By cancellation of the leading bits (this is the intention of the argument reduction) the error inherent in the machine product is amplified significantly. The reduced argument $r$ loses the number of significand bits needed to express $j$ and $i$.
To improve the reduction process we use the accurate dot product of PASCAL-XSC. We express the product $x \cdot \frac{1}{\ln 2}$ by

$$x \cdot \frac{1}{\ln 2} = x(c_1 + c_2) = xc_1 + xc_2.$$

Here $c_1 + c_2 \approx \frac{1}{\ln 2}$ to an accuracy of ca. 106 bits (two double numbers). Using such a representation, the reduced argument $r$ is computed by one accurate scalar product and only one final rounding:

$$r = \square(xc_1 + xc_2 - i - j) \tag{9.38}$$

Because the exponential is a rapidly increasing function the argument range for the computer analogon is limited by the relative small upper bound

$$expmax := \ln(maxreal) \quad = \quad 709.782712893384$$

Therefore maximal $\log_2(710) + 3 < 13$ bits are enough to express the sum $j + i/8$. This shows, that $r$ computed by (9.38) is a floating-point number of full accuracy. Using a staggered representation of $1/\ln 2$ with two floating-point summands suffices to get an accurately reduced argument.

#### 9.6.2.2 Improvement by A Priori Error Estimations

To improve our algorithm in speed we do no longer perform an interval horner scheme for the evaluation of the approximation

$$2^r \approx \sum_{k=0}^{9} q_k r^k.$$

The rounding errors and the errors introduced by the fact, that the polynomial coefficients are in general not exactly representable as floating-point numbers are catched by an a priori error estimation. We can use interval software to find an upper bound for these kinds of error. The algorithm used is a simplified version of a method described in [188]. The theory is discussed in Appendix C. A PASCAL-XSC program called `experr` for automaticly doing an a priori error estimation for the exponential function is also given there.
The actual input data for the program `experr` shown in Appendix C are enclosures $[q_k]$ for the exact polynomial coefficients $q_k = \dfrac{(\ln 2)^k}{k!}$ as well as an enclosure of the basic range $[0, \dfrac{1}{8}]$ covering the reduced argument $r$ of our exponential routine. The output of the program are two positive numbers called $\alpha$ and $\beta$ with

$$\begin{aligned} &\left|\sum q_k r^k - \text{Machine Horner}(\tilde{q}_k, \tilde{r}, k = 0, 1, \ldots, 9)\right| \\ &\leq |p_n(r) - p_n(\tilde{r})| \cdot \alpha \cdot \varepsilon + |p_n(\tilde{r}) - \tilde{p}_n(\tilde{r})| \cdot \beta \cdot \varepsilon(r) \end{aligned} \tag{9.39}$$

for all $r \in [0, \dfrac{1}{8}]$. A quantity $x$ marked by $\tilde{x}$ indicates the floating-point analogon $\tilde{x}$ to the corresponding real quantity $x$. The quantities $\alpha$, $\beta$ are "worst case" quantities. The numerical values comming from Appendix C are

```
Alpha:   0.811837
Beta :   2.428265
```

They are independent of the actual value of $r$.
Due to the accurate argument reduction the relative error $\varepsilon(r) := \left|\dfrac{r - \tilde{r}}{r}\right|$ introduced by the reduction process is bounded by $\varepsilon(r) = \varepsilon = 1.01 \cdot 2^{-53}$. Putting together the derived error bounds and the error bound (9.39) for the approximation error, we find

$$\left|\frac{2^r - \tilde{p}_n(\tilde{r})}{2^r}\right| \underset{(2^r \geq 1)}{\leq} (\alpha + \beta) \cdot \varepsilon + \varepsilon(\text{app}) =: \varepsilon_1 \tag{9.40}$$

To find an over–all error bound for

$$\left|\frac{e^x - \widetilde{\exp}(x)}{e^x}\right|$$

additionally the error coming from the reconstruction given by (see (9.36))

$$(\tilde{p}_n(\tilde{r}) \cdot 2^j) \odot \widetilde{\sqrt[8]{2^i}}$$

has to be considered. The constants $\tilde{c}_i := \widetilde{\sqrt[8]{2^i}}, i = 0, 1, \ldots, 7$ are of maximum accuracy. Thus we get

$$\begin{aligned}
(\tilde{p}_n(\tilde{r}) \cdot 2^j) \odot \widetilde{\sqrt[8]{2^i}} &= p_n(r) \cdot (1+\varepsilon_1) \cdot 2^j \cdot \sqrt[8]{2^i} \cdot (1+\varepsilon)^2 \\
&= p_n(r) \cdot 2^j \cdot \sqrt[8]{2^i} \cdot (1 + \underbrace{\varepsilon_1 + 2.01\varepsilon}_{=:\,\varepsilon_2}) \\
&= e^x \cdot (1+\varepsilon_2) \qquad (9.41)
\end{aligned}$$

The estimation given so far holds for arguments $x \geq 0$. If $x < 0$ a final division which may be accompanied by an additional rounding error has to be performed. In this case

$$\begin{aligned}
e^x &= \frac{1}{(p_n(r) \cdot 2^j \cdot \sqrt[8]{2^i})(1+\varepsilon_2)}(1+\varepsilon) \\
&= \frac{1}{e^{|x|}}(1 + 1.01(\varepsilon_2 + \varepsilon)) \\
&= e^x(1+\varepsilon_3) \qquad (9.42)
\end{aligned}$$

Summarizing all error estimations leads to

$$\left|\frac{e^x - \widetilde{\exp}(x)}{e^x}\right| = \left|\frac{e^x - e^x(1+\varepsilon_3)}{e^x}\right| \leq \varepsilon(\exp) := 5 \cdot 2^{-53}$$

i.e.

$$e^x \in \widetilde{\exp}(x) \cdot [1 - \varepsilon(\exp), 1 + \varepsilon(\exp)]$$

This representation is used to enclose function values $e^x$ for point arguments $x$. A special handling is done for $x = 0$ and for arguments $x < \ln(\text{minreal}) := -709.782\ldots$. In the first case the point result $e^0 = [1, 1]$ is returned. In the second case the interval $[0, \text{minreal}]$ is used as an enclosure of $e^x$.

### 9.6.3 Exponential Function for Interval Arguments

The exponential function is always positive and monotone increasing. To enclose $\exp[\underline{x}, \overline{x}]$ by a floating-point interval we first compute enclosures explb $\ni e^{\underline{x}}$ and expub $\ni e^{\overline{x}}$ using the routine discussed in the preceding paragraph. Then it holds $\exp[\underline{x}, \overline{x}] \subseteq [\inf(\text{explb}), \sup(\text{expub})]$.

#### 9.6.3.1 Algorithms

First the algorithm for the accurate argument reduction is given.

## Algorithm 9.12: AccArgRed $(x, [r], j, i)$ {subroutine}

{$c_1$, $c_2$ are two floating-point numbers, the sum of which approximates $1/\ln 2$ to ca. 106 bits}

1. $accu := x \cdot c_1 + x \cdot c_2$ { accurate scalar product }
2. $h := \square accu$ { $accu$ is a *dotprecision* variable }
3. $j := \mathrm{trunc}(h)$
4. $accu := accu - j$
5. $h := \square(accu)$
6. $i := \mathrm{trunc}\ 8 \cdot h$
7. $h := \square(accu - 0.125 \cdot i)$
8. **return** $r := h, j, i$

The next algorithm shows the approximation of $\exp(x)$ within the basic range $[0,\ 1/8]$. Due to the known a priori error bound only floating-point computations have to be performed.

## Algorithm 9.13: Approx $([r])$ {function}

$s := q_n$ { $q_k = \dfrac{(\ln 2)^k}{k!}$ }

**for** $k := n - 1$ **downto** $0$ **do**

  $s := s \cdot r + q_k$

**return** Approx $:= s$

Algorithm iExp can be used to compute an enclosure of $\exp(x)$, $x$ being a point argument.

## Algorithm 9.14: iExp $(x)$ {function}

{$c_i := 2^{i/8}, i = 0, 1, \ldots, 7$, $\varepsilon(\exp)$ according to (9.37) }

**if** $x > MaxExpArg$ **then**

  $ERROR$

**else if** $x < MinExpArg$ **then**

  $[h] := [0, \mathrm{succ}(0.0)]$

**else if** $x = 0$ **then**

  $[h] := 1$

**else**

  $neg := (x < 0)$

  ArgRedAcc $(\mathrm{abs}(x), r, j, i)$

$s :=$ Approx $(r)$

**if** $neg$ **then**

$[h] := [1 - \varepsilon(\exp), 1 + \varepsilon(\exp)]/(2^j \cdot s \cdot c_i)$

**else**

$[h] := [1 - \varepsilon(\exp), 1 + \varepsilon(\exp)] \cdot 2^j \cdot s \cdot c_i$

{now it holds $e^x \in [h]$ }

**return** iExp $:= [h]$

The final algorithm handles $\exp([x])$ for interval arguments.

## Algorithm 9.15: iExp $([x])$ {function}

**if** $\mathrm{diam}[x] = 0$ **then**

$[h] :=$ iExp $(\inf([x]))$

**else**

$[a] :=$ iExp $(\inf([x]))$

$[b] :=$ iExp $(\sup([x]))$

$[h] := [\inf([a]), \sup([b])]$ {Now $\exp[x] \subseteq [h]$ }

**return** iExp $:= [h]$

Notice: The function calls of iExp $(\ldots)$ in the body of Algorithm 9.15 refer to Algorithm 9.14 (the arguments are **point** arguments!).

### 9.6.3.2 Program Code

We now give the PASCAL-XSC source code for the module `expmi`. It implements the improved exponential version `iExp` which computes an interval enclosure of $\exp([x])$.

```

#### 9.6.3.3 Numerical Examples

The driver program `expmitst` which uses the same (point) arguments already used in the numerical examples following the simple program version (see Subsection 9.6.1.6) is as follows:
listingstdfktn/expmitst.lst The following output is produced:

```
iExp(  0)=[  1.000000000000000E+000,  1.000000000000000E+000 ]
iExp( 50)=[  5.184705528587072E+021,  5.184705528587075E+021 ]
iExp(100)=[  2.688117141816134E+043,  2.688117141816136E+043 ]
iExp(150)=[  1.393709580666379E+065,  1.393709580666380E+065 ]
iExp(200)=[  7.225973768125748E+086,  7.225973768125752E+086 ]
iExp(250)=[  3.746454614502671E+108,  3.746454614502674E+108 ]
Use the intrinsic PASCAL-XSC exp routine:
exp( 250)=[  3.746454614502673E+108,  3.746454614502674E+108 ]
```

Now all enclosures are of high quality.

## 9.7 Logarithm

This section presents two algorithms to bound the range of logarithms. The first algorithm computes $\log_2(x)$. The algorithm discussed in Subsection 9.7.2 is a typical table-driven realization of $\ln(x)$.

### 9.7.1 Enclosing Logarithms

The natural logarithm $\ln x$ is the inverse of $\exp(x)$:

$$\ln(\exp(x)) = \exp(\ln(x)) = x.$$

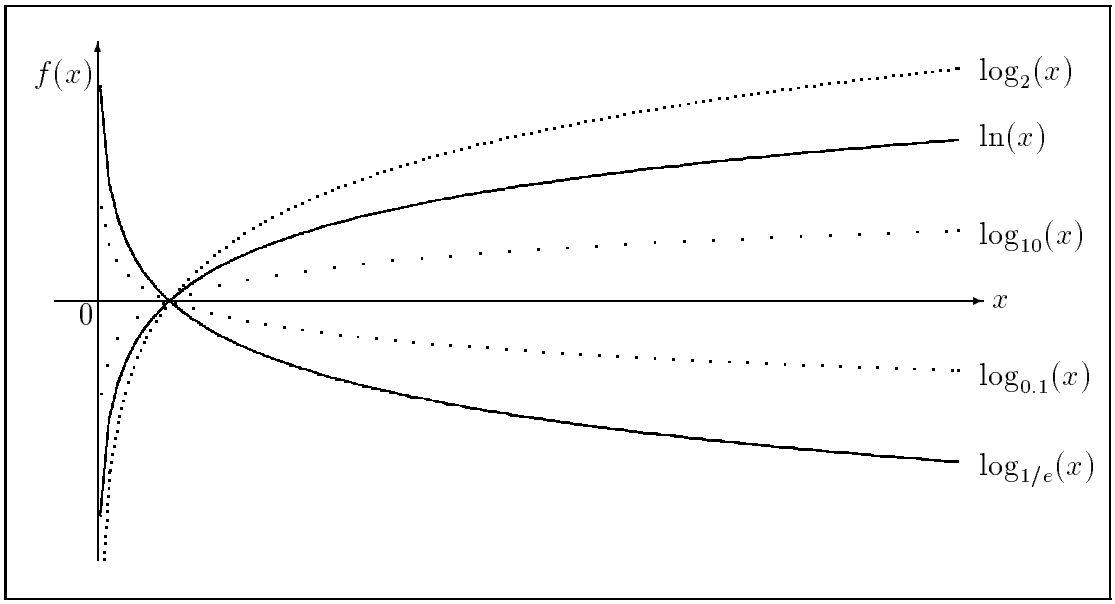

Figure 9.9: Logarithm

It is real only on the positive real axes. In this range it is an increasing function of $x$. Logarithms to other positive bases $b$ may be written in the form

$$\log_b(x) = \ln(x) \cdot \frac{1}{\ln(b)} \tag{9.43}$$

#### 9.7.1.1 Argument Reduction for $\log_2$

To simplify range reduction most logarithm subroutines on binary machines actually compute $\log_2(x)$, and then form the natural logarithm by an additional multiplication

$$\ln(x) = \log_2(x) \cdot \ln(2) \tag{9.44}$$

Writing

$$x = m \cdot 2^n, \tag{9.45}$$

where $n$ is the integer floating-point exponent of $x$ and $m$ its mantissa with

$$\frac{1}{2} \leq m < 1, \tag{9.46}$$

yield

$$\log_2(x) = n + \log_2(m). \tag{9.47}$$

To approximate $\log_2(m)$ we may use

$$\log_2(m) = t \sum_{k=0}^{\infty} q_k \cdot t^{2k}, \; m > 0 \tag{9.48}$$

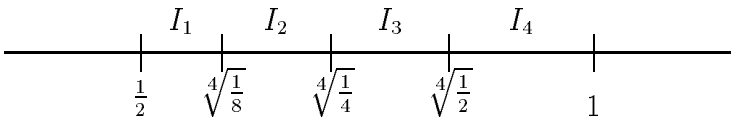

Figure 9.10: Argument Reduction for $\log_2$

with

$$t := \frac{m-1}{m+1}, \quad \text{and} \quad q_k := \frac{2}{(2k+1)\ln 2} \tag{9.49}$$

The range reduction into the basic interval $[1/2, 1]$ indicated by (9.45) and (9.46) requires an approximating function

$$p_N(t) := t \cdot \sum_{k=0}^{N} q_k \cdot t^{2k} \tag{9.50}$$

with $N$ being relative large. Therefore, a further refinement of the reduction process is done. We proceed as follows: The quantity $m$ ranges from 1/2 to 1. This range is now subdivided into 4 parts $I_1, \ldots, I_4$ according to

$$\begin{aligned} I_1 &:= [\tfrac{1}{2}, \sqrt[4]{\tfrac{1}{8}}] \quad , \quad I_2 := [\sqrt[4]{\tfrac{1}{8}}, \sqrt[4]{\tfrac{1}{4}}], \\ I_3 &:= [\sqrt[4]{\tfrac{1}{4}}, \sqrt[4]{\tfrac{1}{2}}] \quad , \quad I_4 := [\sqrt[4]{\tfrac{1}{2}}, 1] \\ \text{i.e.} \quad I_j &:= [\sqrt[4]{\tfrac{1}{2^{4-(j-1)}}}, \sqrt[4]{\tfrac{1}{2^{4-j}}}] \quad , \quad j = 1,2,3,4. \end{aligned} \tag{9.51}$$

The intervals $I_j,\ j = 1,2,3$ are mapped into $I_4$ by multiplying $m \in I_j$ with

$$c_j := \sqrt[4]{2^{4-j}} \tag{9.52}$$

Thus

$$\begin{aligned} \log_2(m) &= \log_2(m \cdot c_j \cdot \frac{1}{c_j}) \\ &= \log_2(m \cdot c_j) + \log_2 \frac{1}{c_j} \\ &= \log_2(m \cdot c_j) - \log_2 \sqrt[4]{2^{4-j}} \\ &= \log_2(m \cdot c_j) - \frac{4-j}{4} \end{aligned} \tag{9.53}$$

The product $r := m \cdot c_j \in [\sqrt[4]{1/2}, 1]$ is transformed into the reduced argument

$$t = t(r) := \frac{r-1}{r+1} = \frac{m \cdot 2^{\frac{4-j}{4}} - 1}{m \cdot 2^{\frac{4-j}{4}} + 1} = \frac{m - 2^{\frac{j-4}{4}}}{m + 2^{\frac{j-4}{4}}} \tag{9.54}$$

The function $t(r)$ is monotone increasing in $r$ ($r \in [\sqrt[4]{1/2}, 1]$). This leads to the basic interval

$$t([\sqrt[4]{1/2}, 1]) = [\frac{\sqrt[4]{1/2} - 1}{\sqrt[4]{1/2} + 1}, 0] \subseteq [-0.0865, 0].$$

#### 9.7.1.2 Approximation Within the Basic Interval

Within this interval the relative approximation error is bounded by

$$\left| \frac{t \sum_{k=0}^{\infty} q_k \cdot t^{2k} - t \sum_{k=0}^{N} q_k \cdot t^{2k}}{t \sum_{k=0}^{\infty} q_k \cdot t^{2k}} \right| = \left| \frac{\sum_{k=N+1}^{\infty} q_k \cdot t^{2k}}{\sum_{k=0}^{\infty} q_k \cdot t^{2k}} \right|$$

$$\leq \frac{1}{q_0} \cdot q_{N+1} \cdot t^{2N+2} \left\{ 1 + \underbrace{\frac{q_{N+2}}{q_{N+1}}}_{\in(0,1)} t^2 + \underbrace{\frac{q_{N+3}}{q_{N+1}}}_{\in(0,1)} t^4 + \ldots \right\} \tag{9.55}$$

$$\leq \frac{1}{q_0} \cdot q_{N+1} \cdot t^{2N+2} \cdot \frac{1}{1-t^2}$$

$$\leq \frac{\ln 2}{2} \cdot \frac{2}{(2N+3)\ln 2} \cdot t^{2N+2} \cdot \frac{1}{1-t^2} = \frac{1}{2N+3} \cdot \frac{t^{2N+2}}{1-t^2}$$

$$\overset{|t|<0.0865}{\leq} \frac{1.1}{2N+3}(0.0865)^{2N+2} \overset{N=7}{<} 0.636 \cdot 10^{-18} =: \varepsilon(app)$$

Putting all together shows

$$\log_2(x) \;=\; n - \frac{4-j}{4} + t \cdot p(t^2) \cdot (1 + \varepsilon_{\text{app}}) \tag{9.56}$$

with

$$t := \frac{m \cdot c_j - 1}{m \cdot c_j + 1} = \frac{m - c_j}{m + c_j} \tag{9.57}$$

if $m \in I_j$, and $x = m \cdot 2^n$, and an appropriate quantity $\varepsilon_{\text{app}} \in [-\varepsilon(\text{app}), \varepsilon(\text{app})]$. For arguments $x \in [1, \sqrt[4]{2}]$ the argument reduction process would give $m \in [1/2, \sqrt{1/8}]$, $n = 1$, $j = 1$ with $\log_2 x = 1 - 3/4 + t \cdot p(t^2) = 0.75 - t \cdot p(t^2)$.

Thus, for $x$ very near to 1 ($\Rightarrow \log_2 x$ close to 0) cancellation of leading bits in $t \cdot p(t^2)$ will occur. In general, the machine approximation of $t \cdot p(t^2)$ will be contaminated by rounding errors. These errors will be amplified dramatically. Therefore, the case $x \in [1, \sqrt[4]{2})$ is handeled separately. In these case we do not separate $x$ into its mantissa $m$ and its exponent $n$. Instead

$$\log_2(x) = \frac{x-1}{x+1} \cdot p_\infty((\frac{x-1}{x+1})^2) \approx \frac{x-1}{x+1} \cdot p_N((\frac{x-1}{x+1})^2) \tag{9.58}$$

is used directly.

The value $\dfrac{x-1}{x+1}$ ranges from 0 to $\dfrac{\sqrt[4]{2}-1}{\sqrt[4]{2}+1} < 0.0865$. Therefore, error estimation (9.55) is valid again.

#### 9.7.1.3 Result Adaptation

If $x \in [1/\sqrt[4]{2}, \sqrt[4]{2}]$ formula (9.58) is used and no reconstruction is necessary. In all other cases the representation (9.58) is used, i.e. $\log_2(x)$ is computed via

$$\log_2(x) = n - \frac{4-j}{4} + t \cdot p_\infty(t^2) \approx n - \frac{4-j}{4} + t \cdot p_N(t^2)$$

$n$ according to (9.45), (9.46), $j$ according to (9.53) and $t$ according to (9.54).

#### 9.7.1.4 Algorithms

The argument reduction is done in the following way:

**Algorithm 9.16:** ArgRed $(x, [r], n, j)$ {procedure}

**if** $\sqrt[4]{\frac{1}{2}} < x < \sqrt[4]{2}$ **then** $\{x$ near to $1\}$
  $[r] := \dfrac{x-1}{x+1}$
  $n := 0$
  $j := 0$
**else**
  $m := \text{mant}(x)$ $\{\in [0.5, 1)\}$
  $n := \text{expo}(x)$ $\{x = m \cdot 2^n\}$
  **if** $m > \sqrt[4]{\frac{1}{4}}$ **then**
    **if** $m < \sqrt[4]{\frac{1}{2}}$ **then** $j = 3$
    **else** $j = 4$
  **else**
    **if** $m < \sqrt[4]{\frac{1}{8}}$ **then** $j := 1$
    **else** $j := 2$

$[h] := m \cdot [c_j]$ $\{2^{\frac{4-j}{4}} \in [c_j]\}$

$[r] := \dfrac{[h]-1}{[h]+1}$

**return** $[r], n, j$

Enclosures for $\log_2(x)$ for point arguments $x$ can be computed via

## Algorithm 9.17: LnSimp $(x)$ {function}

**if** $x \leq 0$ **then** $\{q_k = \dfrac{2}{(2k+1)\ln 2} \in [q_k]\}$
  ERROR
**else if** $x = 1$ **then** $[s] := 0$
**else**
  ArgRed $(x, [r], n, j)$
  $[s] := [q_N]$
  **for** $k := N-1$ **downto** $0$ **do**
    $[s] := [s][r]^2 + [q_k]$
  $[s] := [r][s][1-\varepsilon(\text{app}), 1+\varepsilon(\text{app})]$
  $[s] := [s] + n - \dfrac{4-j}{4}$

**return** LnSimp $:= [s]$

Enclosures for $\log_2([\underline{x}, \overline{x}])$ for interval arguments can be computed by

## Algorithm 9.18: LnSimp $([x])$ {function}

**if** $\text{diam}[x] = 0$ **then** {point argument}
  $[h] :=$ LnSimp $(\underline{x})$ {enclosure of $\ln(\underline{x}) = \ln(\overline{x}) = \ln[x]$}
**else**
  $[a] :=$ LnSimp $(\underline{x})$ {enclosure of $\ln(\underline{x})$}
  $[b] :=$ LnSimp $(\overline{x})$ {enclosure of $\ln(\overline{x})$}
  $[h] := [\underline{a}, \overline{b}]$ {enclosure of $[\ln(\underline{x}), \ln(\overline{x})]$}

**return** LnSimp $:= [h]$

### 9.7.1.5 Program Code

We now give the PASCAL-XSC source code for the module `lnm`. Here the simple program version `LnSimp` which computes an interval enclosure of $\ln(x)$ is implemented.

```
{------------------------------------------------------------------------}

END.
{------------------------------------------------------------------------}
```

#### 9.7.1.6 Numerical Examples

The driver program `lnmtst` computes un upper bound for the relative approximation error over a set of randomly chosen point interval arguments. The function `MaxRelErr` is taken from module `fnc_util` (see Appendix D). The random number generator is described in Chapter 8.

```
PROGRAM lnmtst;          { Driver for module lnm }

USE lnm;      { Use Logarithm Module Simple Version          }
USE i_ari;    { Interval Module                              }
USE random;   { Random numbers                               }
USE fnc_util; { Make available functions Max, MaxRelErr, ... }

VAR x: real;
    a, b: real;
    RelErr, RelErrIntrinsic: real;
    ilnx,           { Enclosure using LnSimp                 }
    lnx: interval;  { Enclosure using the intrinsic routine  }
    k, kmax: integer;
BEGIN
  RelErr:= 0;
  RelErrIntrinsic:= 0;
  a:= sqrt(1/maxreal);
  b:= sqrt(maxreal);
  { a and b are chosen in this way to avoid intermediate overflow     }
  {    within the random number generator RandLn (see module random). }
  kmax:= 4000;
  FOR k:= 0 TO kmax DO BEGIN
    IF k MOD 1000 = 0 THEN BEGIN
      writeln('Number of test cases so far: ', k);
      writeln('   Maximum error for LnSimp:       ', RelErr);
      writeln('   Maximum error for intrinsic ln: ', RelErrIntrinsic);
    END;
    x:= RandLn(a, b); { Logarithmically distributed random numbers in }
                      {   the range a..b.                             }
    x:= x*x; { Cover the full range 1/maxreal..maxreal }
    ilnx:= LnSimp(intval(x));   { Simple routine from module lnm }
    lnx := ln(intval(x));       { PASCAL-XSC intrinsic routine   }
    RelErr:= max( RelErr, MaxRelErr(ilnx, ilnx) );
    RelErrIntrinsic:= max( RelErrIntrinsic, MaxRelErr(lnx, lnx) );
    IF ilnx >< lnx THEN BEGIN   { Check empty intersection       }
      writeln('ERROR: Intersection of intrisic function result and ');
      writeln('  the simple version LnSimp is empty!');
      x:= x/0;  { Force program termination }
    END;
  END; { Loop over k }
END.
```

The driver program `lnmtst` produces the following output:

```
Number of test cases so far: 0
   Maximum error for LnSimp:        0.000000000000000E+000
   Maximum error for intrinsic ln:  0.000000000000000E+000
Number of test cases so far: 1000
   Maximum error for LnSimp:        9.122245242598870E-016
   Maximum error for intrinsic ln:  2.217792472835038E-016
Number of test cases so far: 2000
   Maximum error for LnSimp:        9.122245242598870E-016
   Maximum error for intrinsic ln:  2.217792472835038E-016
Number of test cases so far: 3000
   Maximum error for LnSimp:        1.579564658432300E-015
   Maximum error for intrinsic ln:  2.219349668262382E-016
Number of test cases so far: 4000
   Maximum error for LnSimp:        1.579564658432300E-015
   Maximum error for intrinsic ln:  2.219349668262382E-016
```

We see that the error bound for `LnSimp` is about four times larger than the corresponding bound for the intrinsic PASCAL-XSC routine `ln` .

$$\mathrm{x.}\underbrace{\mathrm{xxxxxx}}_{\hat{=}k}\mathrm{x}\cdots\mathrm{x} \qquad x \in \left[\frac{17}{16}, 2\right)$$

Figure 9.11: $k$ taken from $x$ in Binary Representation

## 9.7.2 Computation of $\ln(x)$ using Table-Lookup

We describe a typical table-lookup algorithm for $\ln(x)$ over the range $[16/17, 2]$.

### 9.7.2.1 Argument Reduction

If $16/17 \leq x \leq 17/16 = 1.0625$ $\ln(x)$ is computed by a polynomial approximation. This polynomial is designed to approximate $\ln(x)$ on $[16/17, 17/16]$. Otherwise, find the breakpoint

$$c_k := 1 + \frac{k}{64}, \quad k \in \{0,\, 1,\, \ldots,\, 64\} \tag{9.59}$$

such that

$$|x - c_k| \leq \frac{1}{128} \tag{9.60}$$

Calculate the reduced argument $r$ by

$$r := \frac{x - c_k}{x + c_k} \quad \in [-\frac{1}{256}, \frac{1}{256}] \tag{9.61}$$

The result of the argument reduction is the index $k \in \{0, \ldots, 64\}$ according to (9.59) in combination with (9.60) as well as the quantity $r$ lying in the basic range $[-2^{-8}, 2^{-8}]$.
Notice that

$$\frac{1+r}{1-r} = \frac{x}{c_k} \quad \in [\frac{255}{257}, \frac{257}{255}] \tag{9.62}$$

holds. In (9.60) the index $k$ may be computed by extracting the first 6 bits after the binary point of $x$.
We compute the appropriate index $k$ by

$$\left.\begin{array}{lcll} h & := & \mathrm{frac}(x) & \\ k & := & \mathrm{trunc}(64 \cdot h) & \\ z & := & x - (1 + \frac{k}{64}) & (\hat{=} x - c_k) \\ \textbf{if} & z > \frac{1}{118} & \textbf{then} & k := k + 1 \end{array}\right\} \tag{9.63}$$

Now it holds

$$|x - (1 + \frac{k}{64})| \leq \frac{1}{128}.$$

#### 9.7.2.2 Approximation Within the Basic Range

In the basic range $r \in [-2^{-8}, 2^{-8}]$ the representation

$$\begin{aligned} \ln(\frac{x}{c_k}) &\overset{(9.62)}{=} \ln\frac{1+r}{1-r} \\ &= r \cdot \sum_{k=0}^{\infty} \frac{2}{2k+1} \cdot r^{2k} \quad =: r \cdot p_\infty(r^2) \end{aligned} \tag{9.64}$$

is exploited. Truncating this series after $n+1$ summands is accompanied by the approximation error

$$\left| \frac{\log_2 \frac{1+r}{1-r} \cdot r \cdot p_n(r^2)}{\log_2 \frac{1+r}{1-r}} \right| = \frac{\sum_{k=n+1}^{\infty} \frac{1}{2k+1} \cdot r^{2k}}{\sum_{k=0}^{\infty} \frac{1}{2k+1} \cdot r^{2k}}$$

$$\begin{aligned} \frac{1}{2n+3} \cdot r^{2n+2} \sum_{k=n+1}^{\infty} \frac{2n+3}{2k+1} \cdot r^{2k-(2n+2)} &\leq \frac{1}{2n+3} \cdot \frac{1}{1-r^2} \cdot r^{2n+2} \\ &\leq 5.08 \cdot 10,\ n := 2, |r| \leq 2^{-8} \end{aligned}$$

I.e. the polynomial

$$r \cdot p_2(r^2) = r \cdot (2 + \frac{2}{3} \cdot r^2 + \frac{2}{5} \cdot r^4) \tag{9.65}$$

approximates $\ln(x/c_k)$ in the basic interval with a relative error bound less than $5.08 \cdot 10^{-16}$. An alternative method would be to compute a best approximating polynomial on the basic range using the algorithm of Remez (see ???).
For $x \in [16/17, 17/16]$ an argument reduction is applied which does not imply an additive reconstruction process. We simply use

$$\ln(x) = \ln\frac{1+r}{1-r} = r \cdot p_\infty(r^2)\,.$$

With $r := (x-1)/(x+1) \in [-1/33, 1/33]$ and $n := 4$ we find as bound for the relative approximation error

$$\left| \frac{\ln(x) - r \cdot p_4(r^2)}{\ln(x)} \right| < \frac{1.01}{???} \cdot (\frac{1}{33})^{10} < 6 \cdot 10^{???} \tag{9.66}$$

#### 9.7.2.3 Result Adaptation

The reconstruction process uses

$$\ln(x) \quad = \quad \ln(c_k) + \ln(\frac{x}{c_k}) \overset{(9.64)}{=} \ln(c_k) + r \cdot p_\infty(r^2) \tag{9.67}$$

The quantities

$$d_k := \ln(c_k),\ k = 0, 1, \ldots, 64 \tag{9.68}$$

are calculated and stored in a table. To get an interval enclosure, we have to use enclosures $[d_k]$ of the reconstruction constants $d_k$. It is enough to store $\bigtriangledown d_k$, $k = 0, \ldots, 64$. Enclosures $[d_k]$ may be computed by $[d_k] := [\bigtriangledown d_k, \mathrm{succ}\bigtriangledown d_k]$. Of course, this results in a small runtime penalty. It is not necessary to store the quantities $c_k = 1 + k/64$ (see (9.63)).

#### 9.7.2.4 Algorithms

We first give the algorithm ArgRed for the argument reduction process.

**Algorithm 9.19:** ArgRed $(x, k, [r])$ {subroutine}

$\{c_k := 1 + \dfrac{k}{64},\ k = 0, 1, \ldots, 64\}$

1. Find $k \in \{0, \ldots, 64\}$ such that
   $|x - c_k| \leq \dfrac{1}{128}$

   {$k$ can be found using the first 6 bits behind the}
   {binary point of $x$ (see page 305) }

2. $[r] := \dfrac{x - c_k}{[x, x] + c_k}$ {enclosure for the reduced argument}
   {computed by interval arithmetic }

**return** $k, [r]$

Notice, that the quantity $x - c_k$ in (9.63) is computed exactly by ordinary floating-point arithmetic. This is not true for the denominator. Therefore, the denominator is forced to be calculated by interval arithmetic.
The next algorithm `iLn` computes an enclosure of $\ln(x)$ for a point argument $x \in [16/17, 2]$ using table lookup.

**Algorithm 9.20:** iLn $(x)$ {function}

$\{a_k := \dfrac{2}{2k+1},\ k = 0, 1 \ldots, n; \quad n = 4,\ p_n(r^2) = \sum_{k=0}^{n} a_k r^{2k}\}$

**if** $x \in [\dfrac{16}{17}, \dfrac{17}{16}]$ **then**

$[r] := \dfrac{x - 1}{[x, x] + 1}$ {expression is computed by interval arithmetic }

$[s] := [r] \cdot p_4([r]^2)$ {interval Horner scheme }
$[s] := [x] \cdot [1 - \mathrm{EpsLn1}, 1 + \mathrm{EpsLn1}]$ {approximation error}

**else**

$\{[d_k] \ni \log_2(c_k) = \log_2(1 + \dfrac{k}{64}),\ k = 0, 1, \ldots, 64\}$

ArgRed $(x, k, [r])$

$[s] := [r] \cdot p_2([r]^2)$ {interval Horner scheme}
$[s] := [s] \cdot [1 - \mathrm{EpsLn2}, 1 + \mathrm{EpsLn2}]$ {approximation error}
$[s] := [s] + [d_k]$ {result adaptation}

**return** iLn $:= [s]$

Based on the enclosure algorithm for point arguments the algorithm `iLn` for interval arguments $[x] \subseteq [16/17, 2]$ is now given:

## Algorithm 9.21: iLn $([x])$ {function}

1. **if** $[x] \not\subseteq [\frac{16}{17}, 2]$ **then**

   ERROR
   STOP
   **else**
   **if** $\mathrm{diam}([x]) = 0$ **then**
   $[z] :=$ iLn $(\underline{x})$
   **else**
   $[u] :=$ iLn $(\underline{x})$
   $[v] :=$ iLn $(\overline{x})$
   $[z] := [\underline{u}, \overline{v}]$

**return** iLn $:= [z]$

### 9.7.2.5 Program Code

We now give the PASCAL-XSC source code for the module `lnmi`. Here the table-driven program version `iLn` which computes an interval enclosure of $\ln([x])$ is implemented.

```
MODULE lnmi;  { Logarithm Module Improved Version  }

USE i_ari;    { Make available interval arithmetic }

CONST
  LnEps1 = 6.0e-17;  { Bound for the approximation error of ln(x), }
                     {   x in [16/17, 17/16] }
  LnEps2 = 5.08e-16; { Bound for the approximation error of ln(x), }
                     {   x in (17/16, 2]     }

VAR                            { Global variables }

Hexadecimal representation of inf(iLn) and sup(iLn):
   3FA00989646B49F5
   3FA00989646B49FC
Hexadecimal representation of inf(ln) and sup(ln):
   3FA00989646B49F6
   3FA00989646B49F7
```

We see that the error bound for `iLn` is about four times larger than the corresponding bound for the intrinsic PASCAL-XSC routine `ln` . To improve the error bound for the table lookup method some constants have to be stored in higher precision (for example as unevaluated sums of two floating-point numbers). Such accurate table-driven routines are described in [314, 315, 316]. To avoid intermediate computations in a higher precision data format, at some rare points a higher precision arithmetic has to be simulated by ordinary IEEEE arithmetic. The determination of reliable a priori error bouds using interval computations may be found in [135].

## 9.8 The Power Function $[x]^{[y]}$

The power function $\mathrm{pwr}([x],[y]) := [x]^{[y]}$ is treated as a function depending on two real interval variables $x$ and $y$. To find an enclosure of the set $R := \{a^b | a \in$

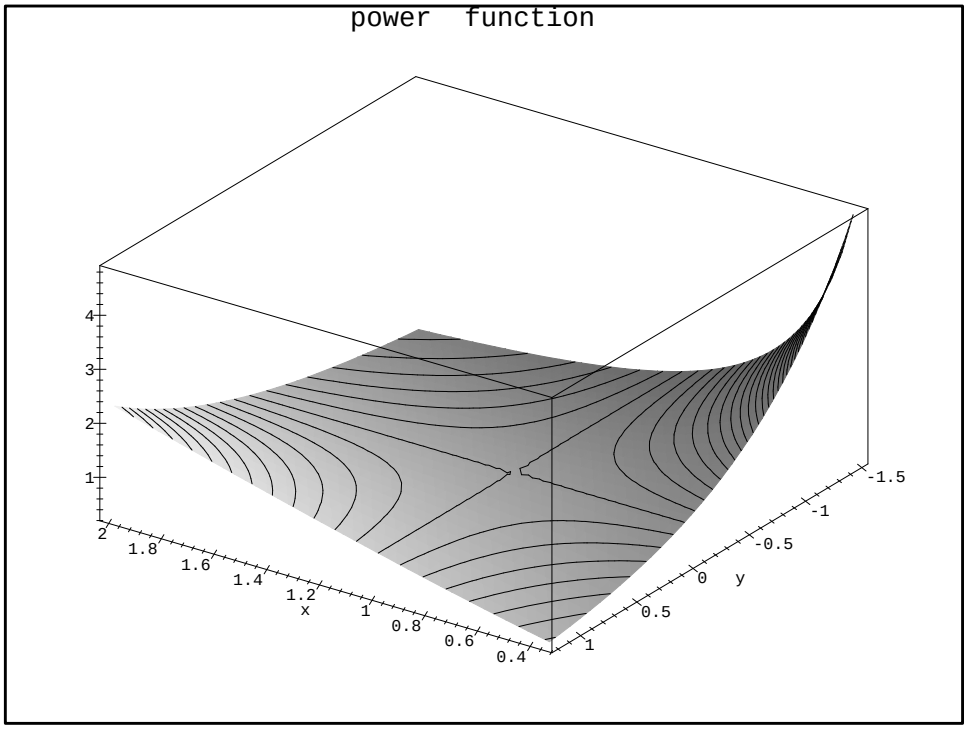

Figure 9.12: Power Function

$[x]$ and $b \in [y]\}$ the extremal point for the minimum function value as well as the extremal point for the maximal function value have to be determined (see Table 9.2). Each extremal value is given as a pair of real values. To find the final inclusion of $R$ the extremal values corresponding to the extremal points are enclosed by intervals. The convex hull of these intervals is a superset of the range of function $R$ for the actual interval arguments $x$ and $y$.

### 9.8.1 Power Function for Point Arguments

The general formula to compute $x^y$ is

$$x^y = \exp(y \cdot \ln(x)).$$

This formula only hold for arguments $x > 0$. In the case $x < 0$ (in this case $y$ must be an integer value) the power $x^y$ is computed by

$$x^y = \pm \exp(y \cdot \ln(\text{abs}(x))).$$

The positive sign holds for even values of $y$, the negative for odd values of $y$. In the case $x = 0$ the function result $x^y = 1$ is returned.
Using interval versions for the exponential function as well as for the natural logarithm inclusions for the power function for point arguments may be computed as shown in Algorithm 1.1.

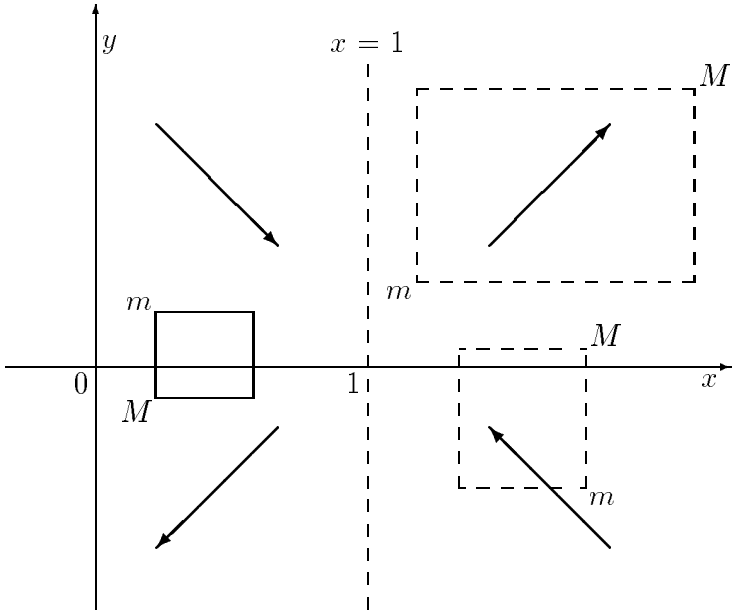

Figure 9.13: Monotonicity behaviour of $\mathrm{pwr}(x, y)$

### 9.8.2 Power Function for Interval Arguments

To handle interval arguments the monotonicity behaviour of $x^y$ with respect to both variables has to be considered. To find the monotonicity behaviour the partial derivatives with respect to $x$ and $y$ may be used. It holds

$$\frac{\partial x^y}{\partial x} = \frac{\partial e^{y \cdot \ln(x)}}{\partial x} = \frac{y}{x}\, e^{y \cdot \ln(x)} ,$$

$$\frac{\partial x^y}{\partial y} = \ln(x) \cdot e^{y \cdot \ln(x)}.$$

The partial derivative with respect to $x$ is positive in the upper right half plane $x > 0,\ y > 0$ and negative in the lower right half plane. The partial derivative with respect to $y$ is negative in the range $0 < x < 1, y \in \mathbb{R}$; it is positive for $x \in (1, \infty), y \in \mathbb{R}$. Consequently, the extremal curves are the $x-$axis $y = 0$ and the vertical line $x = 1$. On these lines one of the partial derivatives is zero. The monotonicity behaviour of the power function is summarized in Figure 9.13. The extremal points are indicated by m and M, respectively.
Table 9.2 shows a complete list of all different cases including values of $\inf(x) \leq 0$. The notation $y \in \mathbb{Z}$ means that $y$ is a point interval with $y_1 = y_2 \in \mathbb{Z}$. The lower bound of the final result is computed in the form $w_1 := \mathrm{pwr}(u, v)$ with $u, v$ being the entries of the column of Table 9.2 indicated by $w_1$. The upper bound is computed using the entries of the column indicated by $w_2$. For example $[0, 0.5] * *[0.1, 0.2]$ leads to case 7 and therefore, to the resulting interval

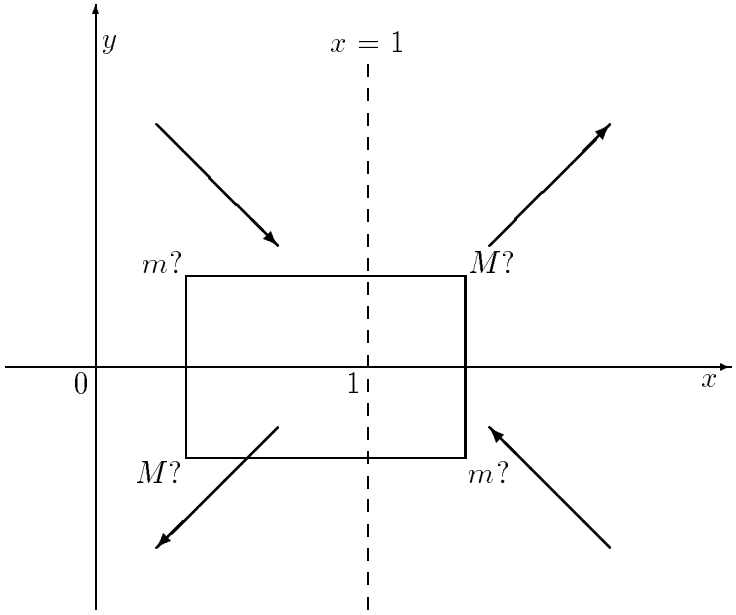

Figure 9.14: pwr($[x]$, $[y]$) with $1 \in [x]$ and $0 \in [y]$

$w = [0, \text{pwr}(x_2, y_2)] = [0.5, \text{pwr}(0.5, 0.2)]$. An error occurs if

- Err1: $0 \in x$; and $y$ is an integer $< 0$ ,
- Err2: $\inf(x) < 0$ and $y \notin \mathbb{Z} \setminus \{0\}$ ,
- Err3: $\inf(x) = 0$ and $0 > \inf(y)$ with $y \notin \mathbb{Z}$.

The program listing of the following section refers to Table 9.2.

### 9.8.3 Algorithms

The power function for point arguments $x$ and $y$. The exact value $x^y$ is an element of the resulting interval returned by the function.

**Algorithm 9.22:** Pwr $(x, y)$ {function}

**if** $x < 0$ **then**
  $[r] := \exp(y \cdot \ln([x, x]))$
  **if** $y \in \{2k + 1 | \; k \in Z\}$ **then** $[r] := -[r]$
**else**
  **if** $x = 0$ **then**

$$w = [w_1,\ w_2] := [x]^{[y]} = [x_1,\ x_2]^{[y_1,\ y_2]}$$

| *Conditions* | | | | | case | $w_1$ | $w_2$ |
|---|---|---|---|---|---|---|---|
| $y_1 = y_2 = 0$ | | | | | 0 | $w_1 = 1$ | $w_2 = 1$ |
| $x_1 < 0$ | $y \in \mathbb{Z}$ | $y_2 \le -1$ | $x_2 \ge 0$ | | Err1 | *Error* | |
| | | | $x_2 < 0$ | $y_2$ even | 1 | $x_1,\ y_1$ | $x_2,\ y_2$ |
| | | | | $y_2$ odd | 2 | $x_2,\ y_1$ | $x_1,\ y_2$ |
| | | $y_2 \ge 1$ | $y_2$ even | $x_2 < 0$ | 3 | $x_2,\ y_1$ | $x_1, x_2$ |
| | | | | $x_2 \ge 0$ | 4 | $w_1 = 0$ | $\max\{\lvert x_1\rvert,\ \lvert x_2\rvert\},\ y_2$ |
| | | | $y_2$ odd | | 5 | $x_1,\ y_1$ | $x_2,\ y_2$ |
| | $(y_1 \ne y_2)$ or $(y_1 \notin \mathbb{Z} \setminus \{0\})$ | | | | Err2 | *Error* | |
| $x_1 = 0$ | $y_1 < 0$ | | | | Err3 | *Error* | |
| | $y_1 \ge 0$ | $x_2 \le 1$ | | $y_1 = 0$ | 6 | $w_1 = 0$ | $w_2 = 1$ |
| | | | | $y_1 > 0$ | 7 | $w_1 = 0$ | $x_2,\ y_1$ |
| | | $x_2 > 1$ | | | 8 | $w_1 = 0$ | $x_2,\ y_2$ |
| $x_1 > 0$ | $x_2 \le 1$ | $y_2 \le 0$ | | | 9 | $x_2,\ y_2$ | $x_1,\ y_1$ |
| | | $y_1 \ge 0$ | | | 10 | $x_1,\ y_2$ | $x_2,\ y_1$ |
| | | $y_1 < 0 < y_2$ | | | 11 | $x_1,\ y_2$ | $x_1,\ y_1$ |
| | $x_1 \ge 1$ | $y_2 \le 0$ | | | 12 | $x_2,\ y_1$ | $x_1,\ y_2$ |
| | | $y_1 \ge 0$ | | | 13 | $x_1,\ y_1$ | $x_2,\ y_2$ |
| | | $y_1 < 0 < y_2$ | | | 14 | $x_2,\ y_1$ | $x_2,\ y_2$ |
| | $1 \in x$ | $y_2 \le 0$ | | | 15 | $x_2,\ y_1$ | $x_1,\ y_1$ |
| | | $y_1 \ge 0$ | | | 16 | $x_1,\ y_2$ | $x_2,\ y_2$ |
| | | $y_1 < 0 < y_2$ | | | 17 | $w_1 = \min\{x_1^{y_2},\ x_2^{y_1}\}$ | $w_2 = \max\{x_2^{y_2},\ x_1^{y_1}\}$ |

Table 9.2: Interval-Logic for the Power Function

$[r] := 0$
**else**
$[r] := \exp(y \cdot \ln([x, x]))$

**return** Pwr:= $[r]$

Here exp and ln refer to interval functions. To emphasize this fact, we use the explicit notation $[x, x]$ to indicate that the real value (point) $x$ is treated as a point interval.
The next algorithm summarizes the computation of the power function for interval arguments.

## Algorithm 9.23: Pwr $([x], [y])$ {function}

1. $x_1 := \underline{x},\ x_2 := \overline{x},\ y_1 := \underline{y},\ y_2 := \overline{y}$
2. Compute an enclosure $[w_1] :=$ Pwr$(u, v)$ with $u \in \{x_1, x_2\}$ and $v \in \{y_1, y_2\}$ being the first and second entry in column '$w_1$' of Table 9.2 corresponding to the actual values of $[x]$ and $[y]$.

   If $w_1 = 0$ or $w_1 = 1$ is indicated, make the corresponding assignment (no additional computation has to be performed). In case 17 compute $[w_1]$ by

   $$[w_1] := \text{interval hull}(\text{Pwr}(x_1, y_2), \text{Pwr}(x_2, y_1)).$$

3. Compute an enclosure $[w_2] :=$ Pwr$(u, v)$ with $u \in \{x_1, x_2, |x_1|, |x_2|\}$ and $v \in \{y_1, y_2\}$ being the first and second entry in column '$w_2$' of Table 9.2. If $w_2 = 1$ is indicated only an assignment is necessary and in case 17 $[w_2]$ is computed by

   $$[w_2] := \text{interval hull}(\text{Pwr}(x_1, y_1), \text{Pwr}(x_2, y_2))$$

4. **if** NO ERROR (see again Table 9.2) **then**

   $[r] := \text{interval hull}([w_1], [w_2])$

5. **return** Pwr:= $[r]$

The interval hull of two intervals $[u]$ and $[v]$ is defined to be

$$\text{intervall hull } ([u], [v]) := [\min\{\underline{u}, \underline{v}\}, \max\{\overline{u}, \overline{v}\}].$$

### 9.8.4 PASCAL-XSC Program Listings

The following program listing shows the PASCAL-XSC module pwr for the computation of interval enclosures of pwr(x,y).

pwrgen: Results are all consistent!
```

The lines ranging from 45 (exclusively) to 49 are caused by invalid arguments. Compare the PASCAL-XSC listing of the module `pwrm.p`. The most important line of the output is the last one.
The values included in file `pwrgen.ref` can be used together with the driver program `pwrtst` to check whether an installation of PASCAL-XSC on an different machines or using a different C compiler on the same machine produces identical results. If the results are not identical with the supplied reference values the installation has to be checked more thoroughly.

# Chapter 10

# Verified Integration

In this Chapter we will discuss some simple methods and programs for the verified computation of definite integrals. Many widely used classes of numerical integration formulas for the determination of the integral

$$I = \int_a^b f(x)dx \tag{10.1}$$

are of the form

$$I = J + R \tag{10.2}$$

where the integral $I$ is approximated by the approximation term $J$ which is the scalar product of certain weights $w_i$ and the function values of $f$ at certain nodes $x_i$:

$$J = \sum_{i=0}^{n} w_i f(x_i) \ . \tag{10.3}$$

The second term $R$ in (10.2) is the remainder term of the integration formula. For sufficiently smooth integrands $f$ this remainder term can often be expressed in a form containing higher derivatives of $f$ at some unknown intermediate points of the interval of integration $[a, b]$.
Integration rules of this type are e.g. the Newton-Côtes formulas, the well known Romberg integration or Gaussian quadrature where in the latter case an additional weight function $w(x)$ appears in the integrand of (10.1).
The basic principle for verified computation of $I$ is the same for all these formulas: we compute enclosures for the function values $f(x_i)$ and compute the scalar product $J$ in interval arithmetic. For the remainder term $R$ we use automatic differentiation (see Chapter 5.1) to compute the higher derivatives which appear in the expression for $R$. The unknown intermediate points are replaced by the interval $[a, b]$ or by suitable subintervals ( e.g. $[x_i, x_{i+1}]$ ) which guarantees that these unknown quantities are enclosed properly.
If an absolute error bound is given which has to be satisfied, we can proceed in the following way: starting from $h_0 = b - a$ we compute for decreasing step sizes $h_i$ enclosures for the remainder term $R$ until its diameter is less than the given absolute error bound. Then we compute an enclosure of the approximation term $J$ for the last step size and add it to the enclosure of the remainder term which results in an enclosure of the integral value. If, however, a relative error bound is given then in

general it is not sufficient to look at the remainder term only in order to decide if the required accuracy is satisfied. Here, in addition, we have to take into account an approximation $J$ for the integral (which needs to be correct only in the order of magnitude, however).
For simplicity we confine ourselves to the widely used Trapezoidal and Simpson's integration rules for which we can follow exactly the pattern outlined above and to Romberg integration, where the approximation term can be computed as scalar product (10.3) or by the well known recursive extrapolation algorithm.

# 10.1 Trapezoidal and Simpson's Rule

## 10.1.1 Theoretical Background

Both, the trapezoidal as well as Simpson's rule are Newton-Côtes formulas. For sufficently smooth functions $f$ the trapezoidal rule

$$I = \frac{b-a}{2}(f(a)+f(b)) \quad - \quad \frac{(b-a)^3}{12}f^{(2)}(\xi), \quad \xi \in [a,b] \tag{10.4}$$

and Simpson's rule

$$I = \frac{b-a}{6}(f(a)+4f(\frac{a+b}{2})+f(b)) \quad - \quad \frac{(b-a)^5}{90}f^{(4)}(\xi), \quad \xi \in [a,b] \tag{10.5}$$

are usually used in the iterated form. This means that we subdivide the interval $[a,b]$ into $n$ equidistant subintervals of length $h = (b-a)/n$ with the nodes $x_i = a + ih, i = 0 \ldots n$. In the case of Simpson's rule $n$ must be even. Now we apply the integration rule on each subinterval separately (on each pair of subintervals for Simpson's rule) and accumulate the approximating terms and the remainder terms. For the trapezoidal rule we then get from $n$ subintervals of length $h$ each

$$I = J_T + R_T \tag{10.6}$$

with the approximating term

$$J_T = \frac{h}{2}\sum_{i=0}^{n}{}^{T}\, 2f(x_i) = \frac{h}{2}(f(x_0)+2f(x_1)+2f(x_2)+\cdots+2f(x_{n-1})+f(x_n)) \tag{10.7}$$

and the remainder term

$$R_T = -\frac{h^3}{12}\sum_{i=1}^{n} f^{(2)}(\xi_i) \tag{10.8}$$

where the first sum is marked with a "T" to indicate that the first and the last term in the summation ( i.e. $f(x_0)$ and $f(x_n)$ ) must be multiplied with a factor of 1 only instead of 2. The second derivative of $f$ is evaluated at unknown intermediate points $\xi_i \in [x_{i-1}, x_i]$ in the second sum.

Similarly, for Simpson's rule we obtain from $n/2$ subintervals of length $2h$ each

$$I = J_S + R_S \tag{10.9}$$

with the approximating term

$$J_S = \frac{h}{3} \sum_{i=0}^{n} s_i f(x_i) \tag{10.10}$$

and the remainder term

$$R_S = -\frac{h^5}{90} \sum_{i=1}^{n/2} f^{(4)}(\xi_i) \tag{10.11}$$

where $s_i = 4$ for $i$ odd and $s_i = 2$ for $i$ even except for $i = 0$ and $i = n$ where $s_0 = s_n = 1$. Again the derivatives in the second sum are evaluated at intermediate points $\xi_i \in [x_{2i-2}, x_{2i}]$ which are in general different from those in (10.8), of course. Now the computation of enclosures for $I$ with either rule is straight forward. We have to compute enclosures of $J_T$ and $R_T$ or for $J_S$ and $R_S$.
To enclose the approximation terms we have to compute enclosures $\diamondsuit f(x_i)$ of the function values of $f$ at the nodes i.e. we have to evaluate $f(x_i)$ in interval arithmetic. Also $J_T$ and $J_S$ are then evaluated in interval arithmetic:

$$J_T \in [J_T] := h \diamondsuit 2 \diamondsuit \diamondsuit \sum_{i=0}^{n}{}^{T} 2 \diamondsuit \diamondsuit f(x_i) \tag{10.12}$$

and

$$J_S \in [J_S] := h \diamondsuit 3 \diamondsuit \diamondsuit \sum_{i=0}^{n} s_i \diamondsuit \diamondsuit f(x_i) \ . \tag{10.13}$$

We can even gain more accuracy if we accumulate the sums in (10.12) and (10.13) by use of a long accumulator i.e. by computing the sums in (10.12) and (10.13) exactly and rounding them only once to a floating-point interval:

$$J_T \in [J_T] := h \diamondsuit 2 \diamondsuit \diamondsuit \sum_{i=0}^{n}{}^{T} 2 \diamondsuit f(x_i) \tag{10.14}$$

and

$$J_S \in [J_S] := h \diamondsuit 3 \diamondsuit \diamondsuit \sum_{i=0}^{n} s_i \diamondsuit f(x_i) \ . \tag{10.15}$$

Enclosures for the remainder terms will be computed by replacing the intermediate points $\xi_i$ by enclosing intervals, i.e. by $[x_{i-1}, x_i]$ for the trapezoidal rule and by $[x_{2i-2}, x_{2i}]$ for Simpson's rule. Evaluating the derivatives of $f$ over these intervals we obtain the enclosures

$$R_T \in [R_T] := -h^3 \diamondsuit 12 \diamondsuit \diamondsuit \sum_{i=1}^{n} \diamondsuit f^{(2)}([x_{i-1}, x_i]) \tag{10.16}$$

and

$$R_S \in [R_S] := -h^5 \diamondsuit 90 \diamondsuit \diamondsuit \sum_{i=1}^{n/2} \diamondsuit f^{(4)}([x_{2i-2}, x_{2i}]) \tag{10.17}$$

Finally the integral $I$ is contained in $[J_T] + [R_T]$ for the trapezoidal rule and in $[J_S] + [R_S]$ for Simpson's rule.
The diameter of $[R_T]$ can easily be estimated by $c_T h^2$ and the diameter of $[R_S]$ by $c_S h^4$ where the constants $c_T$ and $c_S$ do not depend on the step size $h$. Therefore, since the diameter of $[J_T]$ and that of $[J_S]$ are independent of $h$, the diameter of the enclosure of $I$ also decreases with second order in $h$ for the trapezoidal and with fourth order for Simpson's rule.

### 10.1.2 Algorithms

Here we list the verifying algorithms for the trapezoidal rule and for Simpson's rule in Pseudo-Pascal notation.
The termination criterion of the algorithms is chosen as follows: We start with one or two subintervals, compute an enclosure of the remainder term and double the number of subintervals if the diameter of the computed remainder term is not smaller than a user supplied absolute error bound abs_err. We repeat this until the error bound is satisfied or until the diameter of the remainder term starts to increase again. Finally we compute an enclosure of the approximation term and add it to the remainder term to obtain an enclosure of the integral.

**Algorithm 10.1:** Integral $(f, a, b, abs\_err, error)$ {function}

{Trapezoidal Rule with Verification}
**input:** function $f$, integration bounds $a$, $b$ error bound $abs\_err$
**output:** error indicator, function value (enclosure of integral value)

(a) determine number $n$ of subintervals :
$n := 1$
$h := (b-a)/n$
$R := -h^3/12 \cdot \diamondsuit f^{(2)}([a,b])$
**repeat**
$n := 2n$
$h := (b-a)/n$
$R_{old} := R$
$R := -h^3/12 \cdot \diamondsuit \sum_{i=1}^{n} \diamondsuit f^{(2)}([x_{i-1}, x_i])$
**until** $\mathrm{diam}(R) \leq abs\_err$ **or** $\mathrm{diam}(R) > \mathrm{diam}(R_{old})$

(b) compute enclosure of integral :
Integral $:= R + h/2 \cdot \diamondsuit \sum_{i=0}^{n}{}^{T} 2 \diamondsuit f(x_i)$

(c) determine accuracy :
**if** diam(Integral ) $\leq abs\_err$ **then** $error := 0$ {accuracy sufficient}
**else** $error := 1$ {accuracy insufficient}

(d) **return** Integral , $error$

**Algorithm 10.2:** Integral $(f, a, b, abs\_err, error)$ {function}

{Simpson's Rule with Verification}
**input:** function $f$, integration bounds $a, b$, error bound $abs\_err$
**output:** error indicator, function value (enclosure of integral value)

(a) determine number $n$ of subintervals :
$n := 2$
$h := (b-a)/n$
$R := -h^5/90 \cdot \diamondsuit f^{(4)}([a,b])$
**repeat**
$n := 2n$
$h := (b-a)/n$
$R_{old} := R$
$R := h^5/90 \cdot \diamondsuit \sum_{i=1}^{n/2} \diamondsuit f^{(4)}([x_{2i-2}, x_{2i}])$
**until** $\mathrm{diam}(R) \leq abs\_err$ **or** $\mathrm{diam}(R) > \mathrm{diam}(R_{old})$

(b) compute enclosure of integral :
Integral $:= R + h/3 \cdot \diamondsuit \sum_{i=0}^{n} s_i \diamondsuit f(x_i)$

(c) determine accuracy :
**if** diam(Integral ) $\leq abs\_err$ **then** $error := 0$ {accuracy sufficient}
**else** $error := 1$ {accuracy insufficient}

(d) **return** Integral , $error$

### 10.1.3 Applicability of the Algorithms

As already discussed in Section 10.1.1 the algorithms may be applied to any function $f$ which is sufficiently smooth. More precisely, since we compute the derivatives of $f$ by automatic differentiation, we can treat sufficiently smooth functions which are composed of operations and functions from the module itaylor.
Also functions which are nonsmooth at finitely many points in $[a, b]$ may be treated with these algorithms if $[a, b]$ is subdivided such that each of these points is a boundary point of some subinterval and the algorithm is applied in these subintervals.
In certain cases the user required accuracy $abs\_err$ may not be satisfied after completion of the algorithms. This will primarily be the case if the accuracy demand is very high compared to the overestimations which occur in the interval evaluations of $f$ in the approximation term. This may happen especially if the value of the integral is close to zero or if $f$ is a rather complicated expression.

Alternatively a relative error criterion could be used, however, the overestimations will still remain and limit the reachable accuracy. Possible ways out of this situation are the use of higher precision, integration formulas of higher order and adaptive strategies.

### 10.1.4 PASCAL-XSC Program Code

The Algorithms are coded as a global function `INTEGRAL` in a module `itrapez` and a module `isimpson`. `INTEGRAL` takes as input parameters the function $f$ to be integrated as PASCAL-XSC function, the integration bounds `a,b` and the required absolute error `abs_err`. As the functions result it returns an interval enclosing the value of the integral. The parameter `error` returns 0 if the required accuracy could be met otherwise a value of 1 is returned.
Here we remind that the derivatives which are computed in the module itaylor are really Taylor-coefficients, i.e. they are the derivatives of $f$ divided by the corresponding factorials. Therefore the constants used for the computation of the remainder term differ between the program codes and the algorithms.
First we list the module `itrapez` which uses the Trapezoidal rule:

```
MODULE itrapez;

USE itaylor;

{------------------------------------------------------------------------}
{                                                                        }
{ The function integral contained in itrapez computes an enclosure for   }
{ the value of the definite integral of a function f(x) over the interval}
{ [a,b] by use of the iterated trapezoidal rule.                         }
{                                                                        }
{ itrapez uses the operators and functions of the module itaylor for the }
{ computation of the second derivative of f in the remainder term by use }
{ of automatic differentiation.                                          }
{                                                                        }
{ The parameters of the global function integral are                     }
{   f       : function to be integrated, argument and result as itaylor  }
{   a,b     : integration bounds                                          }
{   abs_err : upper bound for the absolute error required from user      }
{   error   : error indicator upon return of function  integral          }
{             error = 0  result meets required accuracy                  }
{             error = 1  result has diameter > abs_err                   }
{                                                                        }
{                                                      b                 }
{   function's result : interval enclosing  integral  f(x) dx            }
{                                                     a                  }
{------------------------------------------------------------------------}

### 10.1.5 Test Results

We consider a simple integral which conains a parameter $c$.

$$I(c) := \int_{-1}^{1} \frac{c^2}{1+(cx)^2} dx \tag{10.18}$$

The exact value of the integral is $I(c) = 2c^{-1}\arctan(c^{-1})$. For large values of $c$ the integrand $f(x) = c^2/(1+(cx)^2)$ exhibits a sharp peak at $x = 0$ which makes the integration difficult for such simple algorithms as our equidistant trapezoidal and Simpson's rules. This can be seen very clearly for the two cases $c = 1$ and $c = 10$. The following short PASCAL-XSC program has been used to compute the results contained in the tables in this section (the program printed here computes the case $c = 10$). For the application of Simpson's rule the use-clause in the program has to be replaced by `USE isimpson;`)

```
PROGRAM example;

USE i_ari,itaylor;
USE itrapez;

FUNCTION f ( x : itaylor ) : itaylor[lb(x)..ub(x)];
BEGIN
   f := 100 / ( 1 + sqr(10*x) );
END;

VAR a,b,abs_err : REAL;
    error       : INTEGER;
    int         : INTERVAL;

BEGIN
   write( 'a,b = ' ); read(a,b);
   REPEAT
      write( 'abs_err = ' ); read( abs_err );
      IF abs_err > 0 THEN
```

```
        BEGIN
           int:= integral( f, a,b, abs_err, error );
           writeln( int, '  ', diam(int):15, error:3 );
        END;
     UNTIL abs_err <= 0;
  END.
```

Table 10.2: Results for I(10) with trapezoidal rule

For increasing demands of accuracy the trapezoidal rule needs excessively many nodes (Tables 10.1 and 10.2) whereas Simpson's rule gets the same accuracy with considerably less nodes reflecting the higher order of Simpson's rule. Especially the case $c = 10$ demonstrates that for an efficient integration algorithm the constant step size must be abandoned and be replaced by a suitable step size adaption. We will revisit this case later in Section 10.2.6 where an adaptive algorithm will be applied with much higher efficiency.
In the tables 10.1 – 10.4 the first column contains the user supplied absolute error bound `abs_err`, in the second column the computed enclosures $[I(c)]$ are listed

whose diameters $d([I(c)])$ can be found in the third column. The fourth column contains the number $n$ of nodes (i.e. function evaluations of $f$) which were used in the integration. The last column is the error indicator of the integration routine which shows if the required accuracy could be satisfied (`error` = 0) or not (`error` = 1).

| `abs_err` | $[I(1)]$ | $d([I(1)])$ | $n$ | `error` |

Table 10.4: Results for I(10) with Simpson's rule

# 10.2 Romberg-Integration

## 10.2.1 Theoretical Background

Romberg integration is a numerical integration method for sufficiently smooth functions which is based on the trapezoidal rule evaluated for different step sizes and supplemented by a suitable extrapolation procedure. It can also be written in the form (10.2) where the remainder term $R$ contains a higher derivative of $f$ and the approximation term $J$ is of the form of a scalar product (10.3).
Usually, however, the weights occurring in $J$ are not used explicitly, but rather $J$ is computed recursively from a so-called extrapolation table. We now give a short description of this recursive computation. For more details see e.g. [309], [94] or [97].
For a sequence of decreasing step sizes $h_0 > \ldots > h_m$ we compute the trapezoidal sums as defined in equation (10.7) which we denote as $T(h_i),\ i = 0, \ldots, m$, here. Then we consider the interpolation polynomials

$$\tilde{T}_{ik}(h) = a_{ik}^{(0)} + a_{ik}^{(1)} h^2 + \ldots + a_{ik}^{(m)} h^{2k}$$

in $h^2$ which interpolates the $k+1$ values $T(h_j),\ j = i-k, \ldots, i$, i.e.

$$\tilde{T}_{ik}(h_j) = T(h_j),\ j = i-k, \ldots, i\ .$$

For each of these polynomials the extrapolated value $\tilde{T}_{ik}(0)$ is in general a better approximation to the integral $I$ than the interpolated values $T(h_j)$. Since $\tilde{T}_{mm}(h)$ interpolates *all* trapezoidal sums $T(h_j),\ j = 0, \ldots, m$, we can expect $\tilde{T}_{mm}(0)$ to be the most accurate approximation of these.
The extrapolated values $\tilde{T}_{ik}(0)$ can be easily computed by use of the Neville-Aitken algorithm (see [309]) without having to determine the interpolating polynomials themselves. We introduce the abbreviations

$$T_{ik} := \tilde{T}_{ik}(0)$$

for the extrapolated values.
Now, $T_{i0} = T(h_i), i = 0, \ldots, m$ and with the Neville-Aitken algorithm (see [309]) we can compute the other values from

$$T_{ik} = T_{i,k-1} + \frac{T_{i,k-1} - T_{i-1,k-1}}{(\frac{h_{i-k}}{h_i})^2 - 1},\quad 1 \le k \le i \le m\ . \tag{10.19}$$

This computation can be arranged in the well-known triangular Romberg-table or T-table (10.20) where the first column contains the values $T_{i,0} = T(h_i)$ of the trapezoidal sums and the following columns are computed by the Neville-Aitken algorithm

(10.19). Thus $T_{ik}$ is contained in row $i$ and column $k$ (if numbering of both is started from zero).

$$
\begin{array}{ccccccccc}
T_{0,0} & & & & & & & & \\
 & \searrow & & & & & & & \\
T_{1,0} & \rightarrow & T_{1,1} & & & & & & \\
 & \searrow & & \searrow & & & & & \\
T_{2,0} & \rightarrow & T_{2,1} & \rightarrow & T_{2,2} & & & & \\
 & \searrow & & \searrow & & \searrow & & & \\
\vdots & & \vdots & & \vdots & & \ddots & & \\
 & \searrow & & \searrow & & \searrow & & \searrow & \\
T_{m,0} & \rightarrow & T_{m,1} & \rightarrow & T_{m,2} & \rightarrow & \cdots & \rightarrow & T_{m,m}
\end{array}
\tag{10.20}
$$

Each $T_{ik},\ i,k \geq 1$, in row $i$ and column $k$ is computed using the values $T_{i-1,k-1}$ and $T_{i,k-1}$ from the left column $k-1$ and the same and the previous rows $i$ and $i-1$ as indicated by the arrows in (10.20).
In our example program we will use for the step sizes the so-called Romberg sequence, which is obtained by successive halvings of $h_0 = b - a$, i.e.

$$h_0 := b - a, \quad h_i := \frac{h_{i-1}}{2} \ .$$

For this special sequence (10.19) becomes

$$T_{ik} = T_{i,k-1} + (T_{i,k-1} - T_{i-1,k-1})/(4^k - 1) \ . \tag{10.21}$$

Another widely used step size sequence is the Bulirsch sequence

$$h_0 := b - a, \quad h_1 := \frac{h_0}{2}, \quad h_2 := \frac{h_0}{3}, \quad h_i := \frac{h_{i-2}}{2}, \quad i \geq 3$$

which has the advantage that for increasing $i$ the number of subintervals and thus the number of function evaluations does not increase as fast as for the Romberg sequence. Thus the computational cost is lower for the Bulirsch sequence. Nevertheless, we stay with the Romberg sequence since the program will be easier to be read for this case. Also, with the Bulirsch sequence some unnecessary roundoff errors are introduced because of the division by 3 for $h_2$ which affects all following $h_{2j}$. This will usually be a minor source for errors only, but it can be reduced by the slightly modified sequence

$$h_0 := b - a, \quad h_1 := \frac{h_0}{2}, \quad h_2 := \frac{5h_0}{16}, \quad h_i := \frac{h_{i-2}}{2}, \quad i \geq 3$$

which can mostly be computed without roundoff errors in floating-point systems with base 2 or 16.
Now we turn to the validated computation of the approximation. Since we can use any of the $T_{ik}$'s as an approximation for $I$ and since for each of them we will later give an explicit representation of the corresponding remainder term $R$ we will compute enclosures for all $T_{ik}$ by a suitable interval evaluation of the Romberg table (10.20).

One possibility to do this would be to use the representation (10.3) for each of the $T_{ik}$, i.e. to compute the weights $w_j = w_j^{(ik)}$ corresponding to the approximation $T_{ik}$ and to evaluate (10.3) by use of a long accumulator. This has been done e.g. in [165], [168], however this requires the computation and storage of many weights which, in addition, depend also on the chosen step size sequence.
Here we choose a different approach, which computes the T-table by use of interval arithmetic, but still uses the long accumulator to accumulate the function values. Therefore the arrangement of our computation of the T-table differs somewhat from what is usually proposed in numerical text books. In most text books the computation of $T(h_i)$ is arranged as follows:

$$T(h_i) = \frac{1}{2}T(h_{i-1}) \; + \; h_i(f(a+h_i) + f(a+3h_i) + \cdots + f(b-h_i)) \; .$$

This, however, is not well suited for interval evaluation, since it introduces too many unnecessary roundings: $T(h_{i-1})$ is a sum which has been rounded to an interval already, and adding the second sum multiplied by $h_i$ adds at least three more roundings and many more if this sum is computed in ordinary interval arithmetic only, i.e. without a long accumulator.
Therefore, we proceed by using two long accumulators, i.e. variables *lo* and *up* of type `DOTPRECISION` in the PASCAL-XSC program, which hold the accumulated values of the trapezoidal sums $T(h_i)$ divided by the step size $h_i$, *lo* for the lower and *up* for the upper bound:

$$\frac{T(h_i)}{h_i} \; \in \; [lo, up]_i := \sum_{j=0}^{n}{}^{T} \; 2 \diamondsuit f(x_j)$$

For increasing values of $i$ the additionally computed function values are further accumulated into $[lo, up]$. At the $i$-th stage the value of $[lo, up]_i$ is rounded once to a floating-point interval and multiplied with the current step size $h_i$ to obtain an enclosure for $T_{i,0}$:

$$T_{i,0} \; \in \; [T_{i,0}] := h_i \diamondsuit [lo, up]_i \; .$$

These enclosing intervals $[T_{i,0}]$ are the values which are actually used for the 0-th column in the T-table. Thus for the starting column we have avoided any unnecessary roundoff errors.
The computation now can be completed by computing an enclosure for each element in the T-table following equation (10.19) or (10.21) for our step size sequence. This computation has to be carried out in interval arithmetic, of course. Thus we obtain enclosures $[T_{i,k}]$, $1 \leq k \leq i \leq m$, for all T-table elements.
The recursive nature of the T-table might give rise to the impression that severe overestimations of the T-table elements may occur. That this will usually not be the case can be seen from the following heuristic case study. Assume, that all enclosures for the trapezoidal sums $T(h_i) = T_{i,0}$ have approximately the same diameter $d_0$. This assumption is reasonable if most values of $f$ are roughly of the same order of

magnitude. This diameter $d_0$ will be amplified through the recursive computation (10.21) to the diameter $d_1$ for the elements $T_{i,1}$ in the next column

$$d_1 = d_0 + (d_0 + d_0)/(4-1) = \frac{5}{3}d_0 = \frac{4+1}{4-1}d_0 \ .$$

Continuing the extrapolation we arrive at

$$d_m = c_m d_0 \quad \text{with} \quad c_m = \frac{4+1}{4-1} \cdot \frac{4^2+1}{4^2-1} \cdots \frac{4^m+1}{4^m-1} \ .$$

The amplification factor $c_m$, however, is rather small here. Some values are:

| $m$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 10 | 20 |
|---|---|---|---|---|---|---|---|---|---|
| $c_m$ | 1.6666 | 1.8888 | 1.9488 | 1.9641 | 1.9679 | 1.9689 | 1.9691 | 1.9692 | 1.9692 |

which shows that the amplification of the diameters is almost negligible. In practice there will also occur some additional roundoff errors, but many examples show that almost never more than one order of magnitude will be lost.
In contrast, however, if we do not compute the trapezoidal sums carefully, then very soon we can loose two or more orders of magnitude up to the last extrapolation.
We close this section with the presentation of the remainder terms $R_{ik}$ which correspond to the approximation terms $T_{ik}$ of the T-table. From [309] we have:

$$\begin{aligned} &I = T_{ik} + R_{ik} \quad \text{with} \\ &R_{ik} = -(b-a)h_{i-k}^2 h_{i-k+1}^2 \cdots h_i^2 \frac{B_{k+1}}{(2k+2)!} f^{(2k+2)}(\xi), \quad \xi \in [a,b] \end{aligned} \tag{10.22}$$

where the $h_j$ are the step sizes and $B_k$ are the Bernoulli numbers. These can be defined by use of the Bernoulli polynomials (see [309]). The first few of the $B_k$ are:

$$\begin{aligned} B_1 &= \frac{1}{6}, & B_2 &= \frac{1}{30}, & B_3 &= \frac{1}{42}, \\ B_4 &= \frac{1}{30}, & B_5 &= \frac{5}{66}, & B_6 &= \frac{691}{2730}, \\ B_7 &= \frac{7}{6}, & B_8 &= \frac{3617}{510}, & B_9 &= \frac{43867}{798} \\ B_{10} &= \frac{174611}{330}, & B_{11} &= \frac{854513}{138} & B_{12} &= \frac{236364091}{2730} \ . \end{aligned} \tag{10.23}$$

We will use only the diagonal entries of the T-table for our algorithm. Thus with the Romberg sequence (10.2.1) as step size sequence the diagonal remainder terms $R_{ii}$ from (10.22) become

$$\begin{aligned} R_{ii} &= -(b-a)h_0^2 \cdots h_i^2 \frac{B_{i+1}}{(2i+2)!} f^{(2i+2)}(\xi) \\ &= -\frac{(b-a)^{(2i+3)}}{2^{i(i+1)}} B_{i+1} \frac{f^{(2i+2)}(\xi)}{(2i+2)!} \ , \quad i = 0, \ldots, m \ . \end{aligned}$$

This is a representation of the $R_{ii}$ which is very similar to the remainder terms for the trapezoidal and Simpson's rule. In order to get enclosures $[R_{ii}]$ we evaluate $R_{ii}$ analogously: $\xi$ is replaced by the interval $[a,b]$ and the derivative of $f$ is computed by automatic differentiation using interval arithmetic. An enclosure $[R_{ii}]$ of $R_{ii}$ thus can be obtained as

$$[R_{ii}] := -(b-a)^{2i+3} \diamondsuit 2^{i(i+1)} \diamondsuit B_{i+1} \diamondsuit (f([a,b]))_{2i+2} \tag{10.24}$$

where $\diamondsuit(f([a,b]))_{2i+2}$ is the Taylor coefficient of order $2i+2$ of $f$ evaluated in interval arithmetic over $[a,b]$.
Now we are in principle ready to compute enclosures for $I$ by use of Romberg integration: if an absolute error parameter `abs_err` is given, we compute the $[R_{ii}]$ for increasing $i$ until we find an index $m$ where the diameter of $[R_{mm}]$ is less than `abs_err`. Then we may use this $m$ to compute an enclosure $[T_{mm}]$ for $T_{mm}$ and finally we have $I \in [T_{mm}] + [R_{mm}]$.
However, we will get a much more powerful algorithm if we embed this simple algorithm in a framework where also the step size may be adapted. This will be the subject of the next Section.

### 10.2.2 An Adaptive Strategy

In this Section we will present a simple procedure to adapt the step sizes of the integration to the behaviour of the integrand $f$. This makes the Romberg integration more powerful and demonstrates how our verifying algorithms may be embedded in a more sophisticated and more efficient framework.
The idea underlying the step size adaption is very simple. Assume we want to obtain an enclosure of $I$ with an absolute error of at most `abs_err`. Then we proceed with a simple bisection method as follows:

**1. Compute:**
First, fix a number $m_{max}$ to be the maximal count of extrapolations being performed on any subinterval. If the required accuracy can be satisfied by using some $m \leq m_{max}$ then the integral is computed by ordinary Romberg integration with $m$ extrapolations on this subinterval. To find such an $m$ we only have to inspect the diameters of the enclosures of the remainder terms $[R_{ii}],\ i = 0, ..., m_{max}$.

**2. Bisect:**
If the error is too large even for $m = m_{max}$ then we bisect the interval and apply our adaptive strategy to both subintervals recursively thereby requiring an absolute error of 0.5*`abs_err` on each subinterval.
To avoid infinite recursion in the bisection step, we force the maximal depth of recursions to stay below some given level `max_depth`. If this level is reached without satisfying the error bounds, then, usually, the whole integral can be computed only with bounds being wider than the required `abs_err`.

Many textbooks recommend to stop the computation of the T-table after approximately seven extrapolations. Following this suggestion, we fix $m_{max} := 7$. For the maximal level for recursions we choose `max_depth` := 20 which allows up to 20 bisections and thus a variation of the step size of six orders of magnitude.
This strategy is certainly not an optimal one and also the choice of the two parameters $m_{max}$ and `max_depth` is only very heuristic. However, the resulting algorithm can be used to compute enclosures for rather complicated and difficult integrals as will be shown in Section 10.2.6.
For more detailed and efficient adaptive verifying methods see [84], [85], [89], [165], [168].

### 10.2.3 Algorithms

Following the discussion in the previous two Sections 10.2.1 and 10.2.2 we present here an adaptive integration algorithm `INTEGRAL` based on Romberg extrapolation. The input for the algorithm are the integrand $f$, the interval of integration $[a, b]$, and an absolute error tolerance `abs_err`. The output are an enclosure of the integral (as function result) and an error code indicating if the required absolute error tolerance could be satisfied or not.
In order to keep the algorithm short we break it into three smaller algorithms where only the third one deals with the step size adaption. The first algorithm, `REMAINDER`, computes enclosures for all remainder terms $[R_{ii}]$ (see 10.24) over the interval $[a, b]$ up to some specified maximal index and returns the first index $m$ for which the diameter of $[R_{mm}]$ is less than the prescribed absolute error bound `abs\_err`.
The second algorithm, `ROMBERG`, computes enclosures for the T-table elements up to the index $m$ which was computed by algorithm `REMAINDER`.
Finally, algorithm `INTEGRAL` calls `REMAINDER` to determine if for a given interval `ROMBERG` can be used to compute an enclosure or if the interval has to be bisected. In the latter case `INTEGRAL` calls itself recursively with the two intervals resulting from bisection and with an error requirement of 0.5*`abs\_err`.

### Algorithm 10.3: Remainder $(f, R, m)$ {procedure}

{Computation of enclosures for Romberg remainder terms}
**input:** function $f$, index $m$ for max. extrapolation count
**output:** first index $m$ of remainder $R_{mm}$ with diam less than *abs_err*, corresponding enclosure $R$ of $R_{mm}$.
**global variables:** integration bounds $a, b$, error bound *abs_err*, these are local variables to algorithm Integral (10.10.5)

$i := 0$
**repeat**
  $i := i + 1$
  $h := b - a$
  $R := -h^{2i+3} \cdot 2^{i(i+1)} \cdot B_{i+1} \diamondsuit(f([a, b]))_{2i+2}$

**until** $(i = m)$ **or** $\mathrm{diam}(R) \leq abs\_err$
**return** $i$, $R$

## Algorithm 10.4: Romberg $(f, m)$ {function}

{Computation of enclosures for the Romberg-table}
**input:** function $f$, index $m$ for extrapolation count
**output:** enclosure of $T_{mm}$ (as function value)
**global variables:** integration bounds $a, b$, these are local variables to algorithm Integral (10.10.5)

$h := b - a$
$l := 1$
$[lo, up] := 0.5 \cdot (f(a) + f(b))$
$t_0 := h \cdot \diamondsuit[lo, up]$
**for** $i := 1$ **to** $m$ **do** {compute trapezoidal sums}
  $h := 0.5 \cdot h$
  $[lo, up] := [lo, up] + \sum_{j=1}^{l} \diamondsuit f(a + (2j-1)h)$
  $t_i := h \cdot \diamondsuit[lo, up]$
  $l := 2 \cdot l$
$q := 1$
**for** $i := 1$ **to** $m$ **do** {compute Romberg table}
  $q := 4 \cdot q$
  **for** $j := m$ **downto** $i$ **do** $t_j := t_j + (t_j - t_{j-1})/(q-1)$
Romberg $:= t_m$

## Algorithm 10.5: Integral $(f, a, b, abs\_err, error)$ {function}

{Romberg Integration with Step Size Adaption and Verification}
**input:** function $f$, integration bounds $a, b$, error bound $abs\_err$
**output:** error indicator, function value (enclosure of integral value)

(a) $depth := depth + 1$ {increase recursion level}

(b) $m := m\_max$ {maximum extrapolation count}

(c) Remainder $(f, R, m)$ {compute remainder $R$ and extrpolation count $m$}

(d) **if** $(\mathrm{diam}(R) > abs\_err)$ **and** $(m = m\_max)$ **and** $(depth \leq max\_depth)$
  **then** {bisection: recursive calls of Integral :}
    $integral\_value :=$ Integral $(f, a, \mathrm{mid}([a, b]), abs\_err/2, error)$
      $+$ Integral $(f, \mathrm{mid}([a, b]), b, abs\_err/2, error)$
  **else** {use T-table and remainder:}
    $integral_value :=$Romberg $(f, m) - R$

(e) Integral $:= integral\_value$ {function result}

(f) {determine accuracy:}
  **if** $\mathrm{diam}(integral\_value) \leq abs\_err$ **then** $error := 0$
  **else** $error := 1$

(g) $depth := depth - 1$ {decrease recursion level}

(h) **return** *error*, Integral

### 10.2.4 Applicability of the Algorithms

Here basically the same restrictions and comments hold which have already been discussed in Section 10.1.3.
However, since we have implemented an adaptive method we can integrate more complicated functions here, than with the simple programs for the trapezoidal and Simpson's rule.

### 10.2.5 PASCAL-XSC Program Code

```
MODULE iromberg;

   { initialize Bernoulli numbers : }
   Ber[ 1]:=      intval(1.0)/  6.0;   Ber[ 2]:=      intval(1.0)/  30.0;
   Ber[ 3]:=      intval(1.0)/ 42.0;   Ber[ 4]:=      intval(1.0)/  30.0;
   Ber[ 5]:=      intval(5.0)/ 66.0;   Ber[ 6]:=    intval(691.0)/2730.0;
   Ber[ 7]:=      intval(7.0)/  6.0;   Ber[ 8]:=   intval(3617.0)/ 510.0;

{ If m_max > 7 then more Bernoulli numbers will be needed : }
{
   Ber[ 9]:=  intval(43867.0)/798.0;   Ber[10]:= intval(174611.0)/ 330.0;
   Ber[11]:= intval(854513.0)/138.0;   ... etc.
}
END.
```

### 10.2.6 Test Results

Since we have written our Romberg algorithm in a more sophisticated way by applying an adaptive strategy of subinterval generation we can try to integrate more difficult functions $f$ than with our simple trapezoidal and Simpson routines. The first example is the same as for the trapezoidal and Simpson's rule, i.e. the integral $I(c)$ from (10.18), here with $c = 10$ only. It shows that our adaptive Romberg algorithm is much more efficient than the simple trapezoidal and Simpson rules. The second examples is a slight modification of one of Bulirsch, [77], which can also be found in [165], [168] and the third one is another example from [165].

**Example 10.1:**

Again we consider the integral $I(10)$ from (10.18). The results which are listed in Table 10.5 were computed with the following short PASCAL-XSC program and demonstrate the superiority of our adaptive Romberg algorithm over the simple

trapezoidal and Simpson rules. The columns of Table 10.5 have the same meaning as in Section 10.1.5, $n$ being the total number of function evaluations over all subintervals.

```
PROGRAM example-romberg1;

USE i_ari,itaylor;
USE iromberg;

FUNCTION f ( x : itaylor ) : itaylor[lb(x)..ub(x)];
BEGIN
   f := 100 / ( 1 + sqr(10*x) );
END;

VAR a,b,abs_err : REAL;
    error       : INTEGER;
    int         : INTERVAL;

BEGIN
   write( 'a,b = ' ); read(a,b);
   REPEAT
      write( 'abs_err = ' ); read( abs_err );
      IF abs_err > 0 THEN
      BEGIN
         int:= integral( f, a,b, abs_err, error );
         writeln( int, '  ', diam(int):15, error:3 );
      END;
   UNTIL abs_err <= 0;
END.
```

| abs_err | $[I(10)]$ | $d([I(10)])$ | $n$ | error |
|---|---|---|---|---|
| 1E+00 | $[29, 30]$ | 5.66E-01 | 160 | 0 |
| 1E-01 | $2.9^{5}_{3}$ | 3.84E-02 | 288 | 0 |
| 1E-02 | $2.942^{4}_{1}$ | 1.04E-03 | 448 | 0 |
| 1E-04 | $2.94225^{6}_{5}$ | 6.24E-06 | 896 | 0 |
| 1E-06 | $2.9422554^{4}_{3}$ | 2.93E-07 | 576 | 0 |
| 1E-08 | $2.942255348^{7}_{5}$ | 7.85E-10 | 832 | 0 |
| 1E-10 | $2.94225534860^{8}_{7}$ | 2.78E-12 | 1536 | 0 |
| 1E-12 | $2.942255348607^{5}_{4}$ | 3.88E-13 | 1728 | 0 |
| 1E-14 | $2.9422553486074^{8}_{6}$ | 8.53E-14 | 2048 | 1 |

Table 10.5: Results for I(10) with adaptive Romberg algorithm

**Example 10.2:**

The integral to be enclosed is

$$I_2 = \int_0^2 2xe^{x^2}\sin(e^{x^2})dx \ . \tag{10.25}$$

The difficulty with this integrand $f(x)$ is that after a very smooth part between $x = 0$ and $x \approx 1$ the function continues with increasingly wild oscillations with rapidly growing amplitude and frequency. Figure 10.1 shows the graph of this integrand.

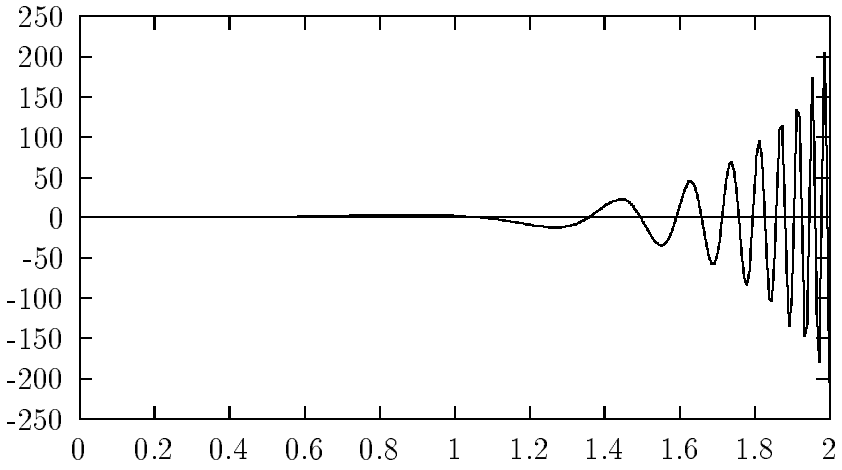

Figure 10.1: $f(x) = 2xe^{x^2}\sin(e^{x^2})$

The integral in (10.25) can be computed exactly as:

$$I_2 = -\cos(e^{x^2})|_0^2 = \cos 1 - \cos e^4 \in 0.910964039265932_8^9$$

We use the following short PASCAL-XSC program to compute enclosures for $I_2$ with the Romberg module for different choices of the error parameter `abs_err`.

```
PROGRAM example-romberg2;

USE i_ari,itaylor;
USE iromberg;

FUNCTION f ( x : itaylor ) : itaylor[lb(x)..ub(x)];
VAR ex : itaylor[lb(x)..ub(x)];
BEGIN
   ex:= exp(sqr(x));
   f := 2*x*ex*sin(ex);
END;

VAR a,b,abs_err : REAL;
    error       : INTEGER;
    int         : INTERVAL;

BEGIN
   write( 'a,b = ' ); read(a,b);
   REPEAT
```

```
      write( 'abs_err = ' ); read( abs_err );
      IF abs_err > 0 THEN
      BEGIN
         int:= integral( f, a,b, abs_err, error );
         writeln( int, '  ', diam(int):15, error:3 );
      END;
   UNTIL abs_err <= 0;
END.
```

From the program we get the enclosures $[I_2]$ in the following Table 10.6. Again the columns in Table 10.6 have the same meaning as in the previous examples.

| abs_err | $[I_2]$ | $d([I_2])$ | $n$ | error |
|---|---|---|---|---|
| 1E+00 | $[0.83, 0.99]$ | 1.48E-01 | 304 | 0 |
| 1E-01 | $0.9_{0}^{2}$ | 8.87E-03 | 352 | 0 |
| 1E-02 | $0.9_{08}^{14}$ | 4.38E-03 | 416 | 0 |
| 1E-04 | $0.9109_{5}^{8}$ | 1.95E-05 | 640 | 0 |
| 1E-06 | $0.91096_{39}^{41}$ | 9.94E-08 | 800 | 0 |
| 1E-08 | $0.9109640_{38}^{40}$ | 9.98E-10 | 928 | 0 |
| 1E-10 | $0.9109640392_{5}^{8}$ | 2.64E-11 | 1376 | 0 |
| 1E-12 | $0.91096403926_{56}^{62}$ | 5.12E-13 | 1728 | 0 |
| 1E-14 | $0.91096403926_{57}^{62}$ | 3.73E-13 | 2496 | 1 |

Table 10.6: Results for $I_2$ with adaptive Romberg algorithm

**Example 10.3:**

The integral to be enclosed in this third example is

$$I_3 = \int_0^4 \left(\frac{1}{a^2 + (3x-1)^2} - \frac{1}{a^2 + (3x-4)^2} + \frac{1}{a^2 + (3x-7)^2} - \frac{1}{a^2 + (3x-10)^2}\right) dx$$

where $a = 0.1$. This is another difficult integral since the integrand has four sharp peaks with maximal values around +100 and -100 and is much smaller between these peaks. See Figure 10.2. Again, this integral can be computed exactly (as sum of several arctan values). We only give an enclosure of $I_3$ obtained from the exact representation:

$$I_3 \in -0.151963942232930_{5}^{6}$$

The graph of the integrand is shown in the following Figure 10.2,
We use the following short PASCAL-XSC program to compute enclosures for $I_3$ with the Romberg module for different choices of the error parameter `abs_err`.

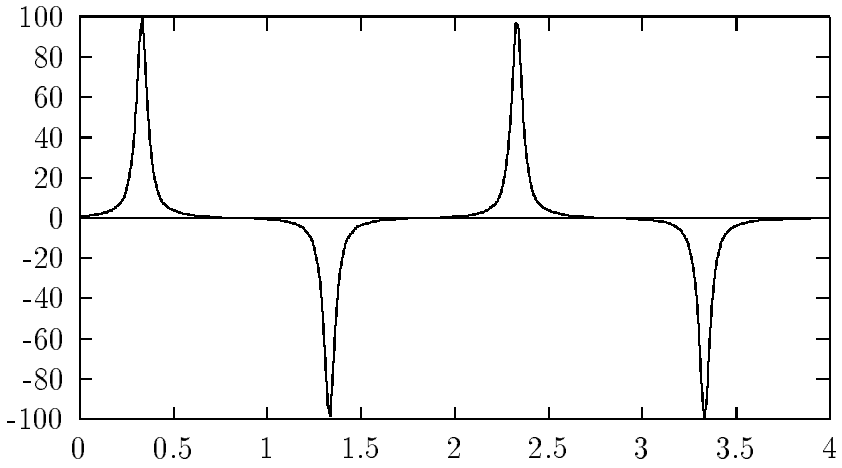

Figure 10.2: $f(x) = \frac{1}{a^2+(3x-1)^2} - \frac{1}{a^2+(3x-4)^2} + \frac{1}{a^2+(3x-7)^2} - \frac{1}{a^2+(3x-10)^2}, \quad a = 0.1$

```
PROGRAM example-romberg3;

USE i_ari,itaylor;
USE iromberg;

FUNCTION f ( x : itaylor ) : itaylor[lb(x)..ub(x)];
BEGIN
  f:= 100 * (  1/(1+sqr(30*x-10)) - 1/(1+sqr(30*x-40 ))
             + 1/(1+sqr(30*x-70)) - 1/(1+sqr(30*x-100)) );
END;

VAR a,b,abs_err : REAL;
    error       : INTEGER;
    int         : INTERVAL;

BEGIN
   write( 'a,b = ' ); read(a,b);
   REPEAT
      write( 'abs_err = ' ); read( abs_err );
      IF abs_err > 0 THEN
      BEGIN
         int:= integral( f, a,b, abs_err, error );
         writeln( int, '  ', diam(int):15, error:3 );
      END;
   UNTIL abs_err <= 0;
END.
```

From the program we get the enclosures $[I_3]$ in the following Table 10.7 where the columns have the same meaning as in the previous examples.

All examples show that even our simple adaptive method can already be successfully used to enclose integrals with rather complicated integrands. The great advantage for the subdivision strategy is the fact that we immediately see the accuracy of the

| abs_err | $[I_3]$ | $d([I_3])$ | $n$ | error |
|---|---|---|---|---|
| 1E+00 | $[-0.29, 0.0066]$ | 2.89E-01 | 1918 | 0 |
| 1E-01 | $-0.1_7^3$ | 3.19E-02 | 1828 | 0 |
| 1E-02 | $-0.1_6^5$ | 3.66E-03 | 1384 | 0 |
| 1E-04 | $-0.1519_7^5$ | 9.36E-06 | 2080 | 0 |
| 1E-06 | $-0.15196_{40}^{39}$ | 3.64E-08 | 4160 | 0 |
| 1E-08 | $-0.1519639_5^4$ | 2.53E-09 | 5120 | 0 |
| 1E-10 | $-0.151963942_3^2$ | 3.51E-11 | 5888 | 0 |
| 1E-12 | $-0.15196394223_{31}^{28}$ | 2.23E-13 | 8640 | 0 |
| 1E-14 | $-0.15196394223_{31}^{28}$ | 1.64E-13 | 10944 | 1 |

Table 10.7: Results for $I_3$ with adaptive Romberg algorithm

partial integrals by computing first an enclosure of the corresponding remainder term. For classical approximation algorithms it is much harder to decide how much the error on some subinterval contributes to the error of the whole integral.

## 10.3 Notes and References

If a verifying version of an integration formula is to be used in the form (10.3) then the nodes $x_i$ and the weights $w_i$ must be represented exactly on the computer or, if this is not possible, enclosures for these quantities must be used. For many classes of integration formulas the weights are rational numbers and the nodes are rational multiples of the end-points $a, b$. Usually these values can be represented exactly in floating-point or a floating-point enclosure of maximum accuracy can be computed trivially.
However, there are also classes like e.g. Gaussian quadrature where the nodes and weights are irrational and may be obtained by complicated algorithms only. Then, in addition to the construction of a verifying numerical integration algorithm, we also must device algorithms for computing enclosures of the nodes and weights. This has been done e.g. for Gaussian quadrature in [311].
A similar problem which is of minor difficulty, however, arises if the integration bounds $a, b$ are not floating-point numbers. Then these must be enclosed in intervals and the integration must be performed over these boundary intervals separately with a very simple rule ( see e.g. [84], [165], [168]. An alternative would be to transform the interval of integration $[a, b]$ to a floating-point interval, $[0, 1]$, say. Then $a, b$ appear as constants in the integrand. However, the evaluation of the transformed integrand could be more sensitive to over-estimations since the bounds $a, b$ are intervals and may appear in many places of the integrand.
More sophisticated integration algorithms do not use equidistant step sizes, but rather adapt the step sizes according to the behaviour of the integrand $f$. We have demonstrated this already with our simple adaptive Romberg integration. Other

more efficient adaptive integration algorithms with verification have been developed e.g. by [84], [85], [89], [165], [166], [167], [168].
Verifying algorithms on the basis of Romberg extrapolation have also been developed for two-dimensional integrals and these can even further be generalized to multi-dimensional integrals. For more details see Storck, [310], [312].

# Appendix A

# The Features of PASCAL–XSC

In this chapter, which is taken from *Numerical Toolbox for Verified Computing I* [124], we give a short overview of the new concepts of the programming language PASCAL–XSC, a universal PASCAL eXtension for Scientific Computation with extensive predefined modules for scientific computation. For a complete language reference and examples, we refer to [173] and [174].
PASCAL–XSC is available for personal computers, workstations, mainframes and supercomputers. Its modern language concepts make PASCAL–XSC a powerful tool for solving scientific problems. The mathematical definition of the arithmetic is an intrinsic part of the language, including optimal arithmetic operations with directed roundings that are directly accessible in the language. Further arithmetic operations for intervals and complex numbers and even for vector/matrix operations provided by precompiled arithmetical modules are defined with maximum accuracy according to the general principle of semimorphism (see Sections ?? and ??).

PASCAL–XSC contains the following features:

- ISO Standard PASCAL
- Universal operator concept (user-defined operators)
- Functions and operators with arbitrary result type
- Overloading of procedures, functions, and operators
- Overloading of the assignment operator
- Module concept
- Dynamic arrays
- Access to subarrays
- String concept
- Controlled rounding
- Optimal (exact) scalar product
- Predefined type *dotprecision* (a fixed-point format to cover the entire range of floating-point products)
- Additional predefined arithmetic types such as *complex, interval, rvector, rmatrix* etc.
- Highly accurate arithmetic for all predefined types

- Highly accurate mathematical functions
- Exact evaluation of expressions (#-expressions)

These new language features are discussed in the following sections.

## A.1 Predefined Data Types, Operators, and Functions

PASCAL–XSC adds the following numerical data types to those available in Standard PASCAL:

| | *complex* | *interval* | *cinterval* |
|---|---|---|---|
| *rvector* | *cvector* | *ivector* | *civector* |
| *rmatrix* | *cmatrix* | *imatrix* | *cimatrix* |

Here, the prefix letters *r*, *i*, and *c* are abbreviations for *real*, *interval*, and *complex*. Hence, *cinterval* means *complex interval*, *cimatrix* denotes complex interval matrices, and *rvector* specifies real vectors. The vector and matrix types are defined as dynamic arrays and can be used with arbitrary index ranges.

PASCAL–XSC also supplies the data type *dotprecision* representing a fixed-point format covering the entire range of floating-point products. The type *dotprecision* allows scalar results — especially sums of floating-point products — to be stored exactly. It is used in connection with *accurate expressions* (see Section A.7).

Many operators are predefined for these types in the arithmetic modules (see Section A.9). All of these operators, as well as the operators for type *real*, deliver results of maximum accuracy.

PASCAL–XSC provides 11 new operator symbols beyond those provided by Standard PASCAL. These are the operators $\circ<$ and $\circ>$, with $\circ \in \{+, -, *, /\}$ for operations with downwardly and upwardly directed rounding, and the operators $**$, $+*$, $><$ needed in interval computations for the intersection, the interval hull, and the test for disjointness, respectively.

Tables A.1, A.2, and A.3 show all predefined operators in connection with the possible combinations of operand types. In Tables A.1 and A.3, the symbol $\triangleleft$ is used as an abbreviation: $\triangleleft \in \{=, <>, <, <=, >, >=\}$. The operators of the first row of Table A.2 are monadic, i.e. there is no left operand. Let $\circ \in \{+, -, *, /\}$, and $\bullet \in \{+, -, *\}$. For vector and matrix types, $*$ denotes the scalar or matrix product.

All usual operations, even those in the higher mathematical spaces, have been realized as operators and can be used in conventional mathematical notation to make programs more easily readable.

Table A.1: Predefined basic operators ($\triangleleft \in \{=, <>, <, <=, >, >=\}$)

| left operand \ right operand | integer | boolean | char | string | **set** |
|---|---|---|---|---|---|
| *monadic* | $+, -$ | **not** | | | |
| integer | $+, -, *, /,$ **div, mod,** $\triangleleft$ | | | | **in** |
| boolean | | **or, and,** $=, <>,$ $<=, >=$ | | | **in** |
| char | | | $+$ $\triangleleft$ | $+$ $\triangleleft$, **in** | **in** |
| string | | | $+$ $\triangleleft$ | $+$ $\triangleleft$, **in** | |
| **set** | | | | | $+, -, *,$ $=, <>,$ $<=, >=$ |
| enumeration type | | | | | **in** |

Table A.2: Predefined arithmetical operators ($\circ \in \{+, -, *, /\}$, $\bullet \in \{+, -, *\}$)

| left operand \ right operand | integer real complex | interval cinterval | rvector cvector | ivector civector | rmatrix cmatrix | imatrix cimatrix |
|---|---|---|---|---|---|---|
| *monadic* | $+, -$ | $+, -$ | $+, -$ | $+, -$ | $+, -$ | $+, -$ |
| integer real complex | $\circ, \circ <, \circ >,$ $+*$ | $+, -, *, /,$ $+*$ | $*, * <, * >$ | $*$ | $*, * <, * >$ | $*$ |
| interval cinterval | $+, -, *, /,$ $+*$ | $+, -, *, /,$ $+*, **$ | $*$ | $*$ | $*$ | $*$ |
| rvector cvector | $*, * <, * >,$ $/, / <, / >$ | $*, /$ | $\bullet, \bullet <, \bullet >,$ $+*$ | $+, -, *,$ $+*$ | | |
| ivector civector | $*, /$ | $*, /$ | $+, -, *,$ $+*$ | $+, -, *,$ $+*, **$ | | |
| rmatrix cmatrix | $*, * <, * >,$ $/, / <, / >$ | $*, /$ | $*, * <, * >$ | $*$ | $\bullet, \bullet <, \bullet >,$ $+*$ | $+, -, *,$ $+*$ |
| imatrix cimatrix | $*, /$ | $*, /$ | $*$ | $*$ | $+, -, *,$ $+*$ | $+, -, *,$ $+*, **$ |

In Table A.3, the operators $<=$ and $<$ denote the subset relations, whereas $>=$ and $>$ denote the superset relations if the operands are interval data types. As already mentioned, $><$ denotes the test for disjointness for interval types. The operator **in** tests for membership of a point in an interval or for strict enclosure of an interval in the interior of another interval. We also call this the inner inclusion relation (see Section ?? for details).

Table A.3: Predefined relational operators ($\triangleleft \in \{=, <>, <, <=, >, >=\}$)

| left operand \ right operand | integer<br>real<br>complex | interval<br>cinterval | rvector<br>cvector | ivector<br>civector | rmatrix<br>cmatrix | imatrix<br>cimatrix |
|---|---|---|---|---|---|---|
| integer<br>real<br>complex | $\triangleleft$ | **in**<br>=, <> | | | | |
| interval<br>cinterval | =, <> | **in**, ><,<br>$\triangleleft$ | | | | |
| rvector<br>cvector | | | $\triangleleft$ | **in**<br>=, <> | | |
| ivector<br>civector | | | =, <> | **in**, ><,<br>$\triangleleft$ | | |
| rmatrix<br>cmatrix | | | | | $\triangleleft$ | **in**<br>=, <> |
| imatrix<br>cimatrix | | | | | =, <> | **in**, ><,<br>$\triangleleft$ |

Compared with Standard PASCAL, PASCAL–XSC provides an extended set of mathematical functions (see Table A.4). These functions are available for the types *integer*, *real*, *complex*, *interval*, and *cinterval* with generic names and deliver results of maximum accuracy.

Table A.4: Predefined mathematical functions

| Function | Generic Name |
|---|---|
| Absolute Value | abs |
| Square | sqr |
| Exponential Function | exp |
| Power Function (Base 2) | exp2 |
| Power Function (Base 10) | exp10 |
| Sine | sin |
| Cosine | cos |
| Tangent | tan |
| Cotangent | cot |
| Hyperbolic Sine | sinh |
| Hyperbolic Cosine | cosh |
| Hyperbolic Tangent | tanh |
| Hyperbolic Cotangent | coth |

| Function | Generic Name |
|---|---|
| | |
| Square Root | sqrt |
| Natural Logarithm (Base e) | ln |
| Logarithm (Base 2) | log2 |
| Logarithm (Base 10) | log10 |
| Arc Cosine | arccos |
| Arc Sine | arcsin |
| Arc Tangent | arctan |
| Arc Cotangent | arccot |
| Inverse Hyperbolic Sine | arsinh |
| Inverse Hyperbolic Cosine | arcosh |
| Inverse Hyperbolic Tangent | artanh |
| Inverse Hyperbolic Cotangent | arcoth |

PASCAL–XSC provides type transfer functions *intval*, *inf*, *sup*, *compl*, *re*, and *im* for conversion between and access to the components of the numerical data types (for scalar, vector and matrix types). Also, some additional functions like *diam*, *mid*, or *transp* for computing diameter and midpoint of an interval or the transpose of a matrix are provided.

## A.2 The Universal Operator Concept

PASCAL–XSC makes programming easier by allowing the programmer to define functions and operators with arbitrary result type. The advantages of these concepts are illustrated by the simple example of polynomial addition. If we define the type *polynomial* by

```
const max_degree = 20;
type  polynomial = array [0..max_degree] of real;
```

in Standard PASCAL, then the addition of two polynomials is implemented as a *procedure*

```
procedure add ( a, b : polynomial; var c : polynomial );
{ Computes c = a + b for polynomials }
var
  i : integer;
begin
  for i := 0 to max_degree do c[i] := a[i] + b[i];
end;
```

Several calls of *add* have to be used to compute the expression $z = a + b + c + d$:

```
add(a,b,z);
add(z,c,z);
add(z,d,z);
```

In PASCAL–XSC, we define a *function* with the result type *polynomial*

```
function add ( a, b : polynomial ) : polynomial;
{ Delivers the sum a + b for polynomials }
var
  i : integer;
begin
  for i := 0 to max_degree do add[i] := a[i] + b[i];
end;
```

Now, the expression $z = a + b + c + d$ may be computed as

```
z := add(a,add(b,add(c,d)));
```

Even clearer is the *operator* in PASCAL–XSC

```
operator + ( a, b : polynomial ) result_polynomial : polynomial;
{ Delivers the sum a + b for polynomials }
var
  i : integer;
begin
  for i := 0 to max_degree do result_polynomial[i] := a[i] + b[i];
end;
```

Now, the expression may be written in the common mathematical notation

```
z := a + b + c + d;
```

A programmer may also define a new name as an operator. A priority is assigned in a priority declaration.

## A.3 Overloading of Procedures, Functions, and Operators

PASCAL–XSC permits the overloading of function and procedure identifiers. A generic name concept allows the programmer to apply the identifiers *sin, cos, exp, ln, arctan*, and *sqrt* not only for *real* numbers but also for intervals, complex numbers, or elements of other mathematical spaces. Overloaded functions and procedures are distinguished by number, order, and type of their parameters. The result type is *not* used for distinction.
As illustrated above, operators also may be overloaded. Even the assignment operator (:=) may be overloaded so that the mathematical notation may be used for assignments:

```
operator := ( var p : polynomial; r : real );
var
  i : integer;
begin
  p[0] := r;
  for i := 1 to max_degree do p[i] := 0;
end;

var
  x : real;
  q : polynomial;
begin
  x := 1.5;
  q := x;   { Polynomial with constant value 1.5 }
end.
```

The overloading concept also applies to the predefined procedures *read* and *write* in a slightly modified way. The first parameter of a newly declared input/output procedure must be a **var**-parameter of file type. The second parameter represents the quantity that is to be input or output. All following parameters are interpreted as format specifications. One could provide an overloaded output facility for polynomials as

```
procedure write ( var t : text; p : polynomial; w : integer );
var
  i          : integer;
  PolyIsZero : boolean;   { Signals 'p' is a zero polynomial }
begin
  PolyIsZero := true;
  for i := 0 to max_degree do
    if (p[i] <> 0) then
    begin
      if PolyIsZero then write(t,'  ')  else  write(t,'+ ');
      writeln(t,p[i]:w,' * x↑',i:1);
      PolyIsZero := false;
    end;
  if PolyIsZero then writeln(t,'   0 (= zero polynomial)');
end;
```

The file parameter is omitted from the calling of an overloaded input/output procedure if the standard file *input* or *output* is assumed. The format parameters must be

introduced and separated by colons. Moreover, several input or output statements can be combined to a single statement as in Standard PASCAL.

```
var
  r : real;
  p : polynomial;
begin
  r := 2;
  p := 5;
  write(p : 7, r : 10, r/5);
end.
```

## A.4 Module Concept

The module concept allows the programmer to separate large programs into modules and to develop and compile them independently of each other. The control of syntax and semantics may be carried out beyond the bounds of the modules. Modules are introduced by the reserved word **module** followed by a name and a semicolon. The body of a module is built up quite similarly to that of a PASCAL program. The significant exception is that the objects to be exported from the module are identified by the reserved word **global** directly in front of the reserved words **const, type, var, procedure, function**, and **operator** and directly after **use**. Moreover, if **global** is placed after the equality sign in a type declaration, then the module exports both the type identifier and the internal structure (e.g. names of components, component types) of the type, which is then called a *non-private* type. Without this second **global**, types are called *private*.
Modules are *imported* into other modules or programs via a **use**-clause. The semantics of the **use**-clause are that all objects declared **global** in the imported module are also known in the importing module or program.
The example of a polynomial arithmetic module illustrates the structure of a module:

```
module poly;

use { Other modules ... }
  utility;

{ Local declarations }
{--------------------}
const
  max_degree = 20;

var
  LocalVariable : integer;

function LocalFunction : real;
var
  Value : real;
begin
  { Do some computations ... }
  LocalFunction := Value;
end;

procedure LocalProcedure;
begin  { Do something ... }  end;
```

```
{ Other local declarations ... }

{ Global declarations }
{--------------------}
global type polynomial = array [0..max_degree] of real;

global procedure read ( var t : text; var p : polynomial );
begin  { Input statements ... }  end;

global procedure write ( var t : text; p : polynomial );
begin  { Output statements ... }  end;

global operator + ( a, b : polynomial ) result_polynomial : polynomial;
{ Delivers the sum a + b for polynomials }
var
  i : integer;
begin
  for i := 0 to max_degree do result_polynomial[i] := a[i] + b[i];
end;

{ Other global declarations ... }

{ Initialization part of the module }
{-----------------------------------}
begin
  LocalVariable := 10;
end. { module poly }
```

## A.5 Dynamic Arrays and Subarrays

The concept of dynamic arrays enables the programmer to implement algorithms independently of the length of the arrays used. The index ranges of dynamic arrays are not defined until run-time. Procedures, functions, and operators may be programmed in a fully dynamic manner, since allocation and release of local dynamic variables are executed automatically. Hence, the memory is used optimally.
For example, a dynamic type *dyn_poly* may be declared:

```
type dyn_poly = dynamic array [*] of real;
```

When declaring variables of this dynamic type, the index bounds have to be specified:

```
var p, q : dyn_poly[0..2*n];
```

where the values of the expressions for the index range are computed during program execution. The two functions *lbound(...)* and *ubound(...)* and their abbreviations *lb(...)* and *ub(...)* access the bounds of dynamic arrays which are specified only during execution of the program. The multiplication of two polynomials may be realized dynamically as follows:

```
operator * ( a, b : dyn_poly ) product : dyn_poly[0..ub(a)+ub(b)];
{ Delivers the product a * b of two dynamic polynomials a, b }
var
  i, j   : integer;
  result : dyn_poly[0..ub(a)+ub(b)];
begin
```

```
  for i := 0 to ub(a)+ub(b) do
    result[i] := 0;
  for i := 0 to ub(a) do
    for j := 0 to ub(b) do
      result[i+j] := result[i+j] + a[i] * b[j];
  product := result;
end;
```

A PASCAL–XSC program using dynamic arrays for polynomials follows the template

```
program dynatest (input, output);
type dyn_poly = dynamic array [*] of real;

operator * ( a, b : dyn_poly ) product : dyn_poly[0..ub(a)+ub(b)];
var
  i, j   : integer;
  result : dyn_poly[0..ub(a)+ub(b)];
begin
  { Statements for the computation of the product ... }
  product := result;
end;

procedure read ( var f : text; p : dyn_poly );
begin  { Input statements ... }  end;

procedure write ( var f : text; p : dyn_poly );
begin  { Output statements ... }  end;

procedure dyn_work (degree: integer);
var
  p, q : dyn_poly[0..degree];
  r    : dyn_poly[0..2*degree];
begin
  writeln('Enter p: '); read(p);
  writeln('Enter q: '); read(q);
  r := p * q;
  writeln('p*q = ', r);
end;

var
  actual_degree : integer;

begin  { Main program }
  write('Enter actual degree: ');  read(actual_degree);
  dyn_work(actual_degree);
end.
```

The following example demonstrates that it is possible to access a row or a column of dynamic arrays as a single object. This is called *slice* notation.

```
program slice;
var
  v    : rvector[1..5];
  A    : rmatrix[1..5,1..5];
begin
  v      := A[2];   { 2nd row of A    }
  A[*,3] := v;      { 3rd column of A }
end.
```

## A.6 Data Conversion

This section is *critical* to the appropriate use of every routine in this book. The concept is simple: People work in a decimal notation, while computers use a binary representation for numbers. The most common error made by even the most experienced interval guru is to forget that numbers such as 0.1 in input data or as literals in the code are *not* what they seem!
Numerical computations nearly always are executed on non-decimal floating-point systems. The floating-point format usually used is a binary format, so it is inevitable that literal *real* constants must be converted into that data format. This conversion can cause an error. For example, the literal constant 1.1 is not exactly representable in a binary format (see Section ?? for details). To execute this conversion in a controlled way, an additional notation for real literal constants is necessary. While the usual PASCAL notation of *real* numbers implies the conversion with rounding to the nearest floating-point (machine) number, it is possible to specify *real* constants that are converted with rounding to the next-smaller or the next-larger floating-point number by the notations

$$(< \pm \textit{Mantissa}\ \mathrm{E}\ \textit{Exponent}\ ) \quad \text{and} \quad (> \pm \textit{Mantissa}\ \mathrm{E}\ \textit{Exponent}\ ) ,$$

respectively. The E and *Exponent* may be omitted as usual, in which case *Mantissa* must contain a decimal point. The parentheses are mandatory. For example, we can program

```
program round_input;
use i_ari;
var
  x, y : real;
  z    : interval;
begin
  x := (< 1.1);                    { Round 1.1 downwardly       }
  y := (> 1.0E-1);                 { Round 0.1 upwardly         }
  z := intval( (< 0.1), (> 0.1) ); { Enclose 0.1 in an interval }
end.
```

To realize a controlled rounding when entering *real* data from the console or from a text file, the procedures *read* (or *readln*) provide an additional format control parameter $r$. This *integer* parameter specifies the rounding mode of the *real* value during the input process. The value of a variable $x$ of type *real* can be entered by

```
read(x : r);
```

which causes the value to be rounded (cf. Section ??):

| | |
|---|---|
| $r < 0$ | round to the next-smaller representable number, |
| $r = 0$ (or absent) | round to the nearest representable number, or |
| $r > 0$ | round to the next-larger representable number. |

A rounding parameter can also be used to convert a string representing a literal *real* constant into a *real* value. Moreover, similar rules apply to the output of *real* values and to their conversion into strings.

## A.7 Accurate Expressions (#-Expressions)

The implementation of algorithms with automatic result verification or validation in this book makes extensive use of the accurate evaluation of dot product expressions, i.e. expressions which can be reduced to a single dot product. This includes matrix and vector expressions, where the computation of each component can be reduced to such a dot product form.
To evaluate this kind of expression, the new data type *dotprecision* was introduced. This data type accommodates the full floating-point range with double exponents (see [211] or [217]). *Accurate expressions* (#-expressions) can be formed based on this data type by an accurate symbol (#, #∗, #<, #>, or ##) followed by an *exact expression* enclosed in parentheses. The exact expression must have the form of a dot product expression in scalar, vector, or matrix structure and is evaluated without any rounding error. Because of this, the result of an accurate expression is of maximum accuracy in the sense that in every component of the result there is no floating-point number between the exact value and the computed one. That is, the rounded and the exact result differ at most by 1 unit in the last place of the mantissa.
To obtain the unrounded or correctly rounded result of a dot product expression, you need to parenthesize the expression and precede it by the symbol #, optionally followed by a symbol for the rounding mode. Table A.5 shows the possible rounding modes for the dot product expression form.

Table A.5: Rounding modes for accurate expressions

| Symbol | Expression Form | Rounding Mode |
|---|---|---|
| #∗ | scalar, vector or matrix | nearest |
| #< | scalar, vector or matrix | downwards |
| #> | scalar, vector or matrix | upwards |
| ## | scalar, vector or matrix | smallest enclosing interval |
| # | scalar only | exact, no rounding |

In practice, dot product expressions may contain a large number of terms making an explicit notation very cumbersome. To alleviate this difficulty in mathematics, the symbol $\sum$ is used. For instance, if $A$ and $B$ are $n$-dimensional matrices, then the evaluation of

$$d = \sum_{k=1}^{n} A_{i,k} \cdot B_{k,j}$$

represents a dot product expression. PASCAL–XSC provides the equivalent shorthand notation **sum** for this purpose. The corresponding PASCAL–XSC statement for this expression is

```
d := #( for k:=1 to n sum( A[i,k] * B[k,j] ) );
```

where $d$ is a *dotprecision* variable.

Accurate or dot product expressions are used mainly in computing a residual. In the case of a linear system $Ax = b$, $A \in \mathbb{R}^{n\times n}$, $x, b \in \mathbb{R}^n$, with $Ay \approx b$, an enclosure of the residual $b - Ay$ can be computed as

```
##( b - A * y );
```

We emphasize that there is only one interval rounding operation per component. To get verified enclosures for linear systems of equations, it may be necessary to evaluate an enclosure of the residual $I - RA$ where $R \approx A^{-1}$ and $I$ is the identity matrix. This can be programmed as

```
##( id(A) - R * A );
```

where an interval matrix is computed with only one rounding operation per component. The function *id(...)* generates an identity matrix of appropriate dimension according to the shape of A (see Section A.9).

## A.8 The String Concept

The tools provided for handling strings in Standard PASCAL do not allow convenient text processing. For this reason, PASCAL–XSC includes a string concept for the convenient handling of textual information and symbolic computation. With this new data type *string*, you can work with strings of up to *maxint* characters, by specifying a maximum string length less than *maxint* in the declaration part. Thus, a string *s* declared by

```
var s : string[40];
```

can be up to 40 characters long. The following string operations are available:

- concatenation of strings (operator +)
- actual length of a string (function *length*)
- conversions *string* → *real*, *string* → *integer*, *real* → *string*, and *integer* → *string* (functions *rval*, *ival*, and *image*)
- extraction of substrings (function *substring*)
- position of first appearance of a string in another string (function *pos*)
- comparisons (relational operators <=, <, >=, >, <>, =, and **in**)

## A.9 Predefined Arithmetic Modules

The following predefined arithmetic modules are available:

- interval arithmetic (*i_ari*)
- complex arithmetic (*c_ari*)

- complex interval arithmetic (*ci_ari*)
- real matrix/vector arithmetic (*mv_ari*)
- interval matrix/vector arithmetic (*mvi_ari*)
- complex matrix/vector arithmetic (*mvc_ari*)
- complex interval matrix/vector arithmetic (*mvci_ari*)

These modules may be imported via the **use**-statement described in Section A.4. As an example, Table A.6 shows the operators provided by the module for interval matrix/vector arithmetic.

Table A.6: Predefined arithmetic and relational operators from module *mvi_ari*

| left operand \ right operand | integer real | interval | rvector | ivector | rmatrix | imatrix |
|---|---|---|---|---|---|---|
| monadic | | | | +, − | | +, − |
| integer real | | | | * | | * |
| interval | | | * | * | * | * |
| rvector | | *, / | +* | +*, +, −, *, **in**, =, <> | | |
| ivector | *, / | *, / | +*, +, −, *, =, <> | +*, **, +, −, *, **in**, =, <>, ><, <=, <, >=, > | | |
| rmatrix | | *, / | | * | +* | +*, +, −, *, **in**, =, <> |
| imatrix | *, / | *, / | * | * | +*, +, −, *, =, <> | +*, **, +, −, *, **in**, =, <>, ><, <=, <, >=, > |

In addition to these operators, the module *mvi_ari* provides the following generically named standard operators, functions, and procedures

*intval, inf, sup, diam, mid, blow, transp, null, id, read*, and *write*.

The function *intval* is used to generate interval vectors and matrices, whereas *inf* and *sup* are selection functions for the infimum and supremum of an interval object. The diameter and the midpoint of interval vectors and matrices are determined via *diam* and *mid*. *Blow* yields an interval inflation, and *transp* is used to get the transpose of a matrix (refer to Chapter **??** for details on the mathematical meaning of these terms).
Zero vectors and matrices are generated by the function *null*, while *id* returns an identity matrix of appropriate shape. Finally, there are the generic input/output procedures *read* and *write*, which may be used in connection with all matrix/vector data types defined in the modules mentioned above.

## A.10 Why PASCAL–XSC?

As already said in the introduction of this book, PASCAL–XSC is the language in which all our "tools" are implemented. The reason for this is that its wide range of modern language concepts for scientific computation makes PASCAL–XSC a powerful tool for solving scientific problems and especially well suited as a specification language for programming with automatic result verification. Moreover, PASCAL–XSC is available for personal computers, workstations, mainframes and supercomputers, and so it supports a high degree of portability among very different computers for all our routines, modules, and programs.
see Toolbox I

# Appendix B

# Additional Remarks Concerning the Data Type *real*

In Section 9.2 the most important features of the data type `real` have been already discussed. We now consider special `real` values as signaling and quiet NaNs in more detail.
By default the PASCAL–XSC runtime assumes that a signaling NaN is identified by bit 51 of the representation of the floating-point number being set. A quiet NaN is identified by bit 51 of the representation of the floating-point number being not set. The sign of a NaN is ignored. The described interpretation of bit 51 is the default setting and may be altered when hardware operations are used for the current installation. Refer to the *local configuration guide* for the actual setting.
A quiet NaN is generated instead of a *real value* if an exception occurred in an operation that does not produce any reasonable arithmetic result due to the exception (invalid operation) and the trap handler is disabled for this exception. The structure of a generated quiet NaN is given in Figure B.1.

| | | | |
|---|---|---|---|
| bit | 63 | = 0 or 1 | (sign is ignored) |
| bit | 62-52 | = 2047 | (all bits are set) |
| bit | 51 | = 0 | (identifies quiet NaN) |
| bit | 32-50 | = 0 | (reserved) |
| bit | 0-31 | = *integer* | (exception code) |

Figure B.1: Structure of a quiet NaN

Module *x_real* contains additional constants, types, functions, and procedures for an extended or alternative processing of *real* values (see Section ??). Especially it supports a new data type called `x_ccode` to distinguish different classes of `real` (IEEE exceptions).

## B.1 Classification of *real* values (Module *x_real*)

Module *x_real* contains additional constants, types, functions, and procedures for an extended or alternative processing of *real* values (see Section ??). Especially it

supports a new data type called `x_ccode` to distinguish different classes of `real` (IEEE exceptions).
The specification of the *real* data type in section 9.2 suggests a classification of *real* values according to the represented value. A total of 10 different classes of *real* values can be distinguished. The data type *x_ccode* is introduced which enumerates the classification codes using enumeration constants.

```
type x_ccode = ( x_sNaN,  { signaling NaN         }
                 x_qNaN,  { quiet NaN             }
                 x_minf,  { minus infinity        }
                 x_mnor,  { negative normalized   }
                 x_mden,  { negative denormalized }
                 x_mnul,  { minus zero            }
                 x_pnul,  { plus zero             }
                 x_pden,  { positive denormalized }
                 x_pnor,  { positive normalized   }
                 x_pinf   { plus infinity         }
               );

function x_class ( r : real ) : x_ccode;
```

The return code of function *x_class* is the classification code of type *x_ccode* of the given *real* value argument.

```
function x_value ( c : x_ccode ) : real;
```

The *real* value returned by function `x_value` is a special value corresponding to the given classification code of type *x_ccode*. The returned value for the classification codes are listed in the following table.

| code | hexadecimal value | description |
|---|---|---|
| `x_sNaN` | `7ff80000ffffffff` | signaling NaN |
| `x_qNaN` | `7ff00000ffffffff` | quiet NaN |
| `x_minf` | `fff0000000000000` | minus infinity |
| `x_mnor` | `ffefffffffffffff` | negative normalized |
| `x_mden` | `8000000000000001` | negative denormalized |
| `x_mnul` | `8000000000000000` | minus zero |
| `x_pnul` | `0000000000000000` | plus zero |
| `x_pden` | `0000000000000001` | positive denormalized |
| `x_pnor` | `7fefffffffffffff` | positive normalized |
| `x_pinf` | `7ff0000000000000` | plus infinity |

Note, that the values returned for `x_sNaN` and `x_qNaN` depend on the installation of your system. Refer to the *local configuration guide*.

## B.2 IEEE Exception Handling Routines

In order to manipulate the exception handling environment of IEEE exceptions, a number of constants are defined which can be used together with the PASCAL–XSC procedures `IEEE_environment` and `IEEE_trap_enable`.

```
IEEE_INV_OP
IEEE_DIV_BY_ZERO
IEEE_OVERFLOW
IEEE_UNDERFLOW
IEEE_INEXACT
IEEE_ALL

IEEE_CONTINUE
```

The constants `IEEE_INV_OP`, `IEEE_DIV_BY_ZERO`, `IEEE_OVERFLOW`, `IEEE_UNDERFLOW`, and `IEEE_INEXACT` characterize the five exceptions specified by the IEEE standard. The constant `IEEE_CONTINUE` is used for changing the exception environment.

```
procedure IEEE_environment(action  : integer;
                           handler : integer;
                           mode    : boolean);
```

Procedure `IEEE_environment` transfers an '`action`' code to the embedding environment of an IEEE exception handler which is selected by the *integer* argument 'handler'. The '`mode`' value activates a characterization if it is *true* or inactivates a characterization if it is *false*.
The '`action`' code

```
IEEE_CONTINUE
```

forces the environment to continue processing after the trap handler has terminated. Other codes may be provided by further releases of the PASCAL–XSC runtime system. The trap handler is identified by the *integer* argument '`handler`' which may have one of the values `IEEE_DIV_BY_ZERO`, `IEEE_INEXACT`, `IEEE_INV_OP`, `IEEE_OVERFLOW`, and `IEEE_UNDERFLOW`. The value of `mode` must be *true* in order to activate this characteristic of the exception handling environment. If `IEEE_CONTINUE` is selected and '`mode`' is *false*, then processing is aborted after leaving the trap handler. Otherwise the processing of the program is continued.

```
procedure IEEE_trap_enable(handler : integer; mode : boolean);
```

Procedure `IEEE_trap_enable` sets the enabled status of an IEEE exception handling routine. If the value of `mode` is *true* then the trap handler is enabled. If the value of `mode` is *false*, then the trap handler is disabled. The selection of the trap handler is done by the value of the *integer* argument `handler` which may have one of

the values IEEE_DIV_BY_ZERO, IEEE_INEXACT, IEEE_INV_OP, IEEE_OVERFLOW, and IEEE_UNDERFLOW.
An example for the usage of the procedures IEEE_environment and IEEE_trap_enable is given in Appendix ?? *IEEE Exception Handling Environment*.

```
function IEEE_test(handler : integer) : boolean;
```

Function IEEE_test returns the value of the exception flag that is associated with the IEEE exception identified by 'handler'. The exception flag is not changed by this function. Exceptions flags stay *set* until they are explicitly *reset* via calls to procedure IEEE_reset.
Before processing the first PASCAL–XSC statement all exception flags are reset. Note that the first PASCAL–XSC statement may be placed in an included module and may affect the exception flags before processing the first statement of the program body. Thus, if IEEE exception handling routines are used, it is recommended that all exception flags are explicitly reset in the program body before processing is started.
The exception flag is set explicitly by the user via procedure 'IEEE_set' or automatically by all IEEE floating-point operations if the corresponding exceptional conditions are met. Exception flags are set independent of the enabled status of the related trap handler. Valid numbers for the *integer* argument 'handler' are IEEE_DIV_BY_ZERO, IEEE_INEXACT, IEEE_INV_OP, IEEE_OVERFLOW, and IEEE_UNDERFLOW.

```
procedure IEEE_set(handler : integer);
```

Procedure IEEE_set sets the value of the exception flag that is associated with the IEEE exception identified by 'handler'. Valid numbers for the *integer* argument 'handler' are IEEE_ALL, IEEE_DIV_BY_ZERO, IEEE_INEXACT, IEEE_INV_OP, IEEE_OVERFLOW, and IEEE_UNDERFLOW. If IEEE_ALL is selected, then all IEEE flags are set.

```
procedure IEEE_reset(handler : integer);
```

Procedure IEEE_reset resets the value of the exception flag that is associated with the IEEE exception identified by 'handler'. Valid numbers for the *integer* argument 'handler' are IEEE_ALL, IEEE_DIV_BY_ZERO, IEEE_INEXACT, IEEE_INV_OP, IEEE_OVERFLOW, and IEEE_UNDERFLOW. If IEEE_ALL is selected, then all IEEE flags are reset.

```
procedure IEEE_save(var x : integer);
```

Procedure IEEE_save saves the setting of all IEEE exception flags and all IEEE trap enabled flags as value of the integer variable 'x'. The complete flag settings saved in variable 'x' may be restored by calling IEEE_restore with argument 'x'

```
procedure IEEE_restore(x : integer);
```

Procedure IEEE_restore restores the setting of all IEEE exception flags and all IEEE trap enabled flags from the integer value 'x'.

# Appendix C

# Reliable Error Bounds for Horner's Scheme

We will derive an algorithm to find an a priori error bound for the maximum relative error caused by inexact (not representable) polynomial coefficients and by the usage of machine operations instead of exact operations for the computation of a polynomial using Horner's scheme. It is assumed that a reliable relative error bound for the accuracy of the coefficients of the polynomial is known (for example: all coefficients are computed with maximum accuracy, i.e. they are known to 0.5 units in the last place). Additionally, a relative error bound for the argument $x$ is assumed to be known (in general, $x$ will be the reduced argument and so its machine counterpart $\tilde{x}$ will be afflicted by rounding errors). The usage of an interval arithmetic enables us to compute the desired bound automatically by a computer.

## C.1 Theory and Algorithmic Description

Typically we are interested in error bounds for expressions like

$$\begin{aligned} &\left| \frac{xP_n(x) - \tilde{x} \odot \tilde{P}_n(\tilde{x})}{xP_\infty(x)} \right| \\ &\qquad \leq \ldots \leq \left| P_n(x) - \tilde{P}_n(\tilde{x}) \right| \frac{1}{\min\limits_x |P_\infty(x)|} + 1.1 \cdot \{\varepsilon(l) + \varepsilon(x)\}. \end{aligned} \tag{C.1}$$

Here $P_\infty(x) = \sum_{k=0}^{\infty} a_k x^k$ denotes a series expansion, $P_n(x)$ its $n$-th partial sum, $\varepsilon(x)$ the relative error of $\tilde{x}$ of $x$ and $\varepsilon(l) := \varepsilon^* = 0.5B^{1-l}$ means Wilkinson's epsilon for an $l$-digit arithmetic with respect to base $B$. It is assumed that $\varepsilon(x)$ and $\varepsilon(l)$ are smaller than $10^{-3}$ . This assumption is almost always fulfilled in practice.
The representation in general $x \cdot P_n(x)$ allows to split off the root of the approximation within the reduced range, (i. e. $\min |P_\infty(x)| > 0$ ). Thus, a bound for the relative error may be estimated. Most work to be done for the error estimation (C.1) belongs to the computation of a bound for the absolute error $\left| P_n(x) - \tilde{P}_n(\tilde{x}) \right|$. This expression will be discussed in the sequel in more detail.

### C.1.1 Error Estimation for $\left|P_n(x) - \tilde{P}_n(\tilde{x})\right|$

To estimate the error $\left|P_n(x) - \tilde{P}_n(\tilde{x})\right|$ we split the formula in two parts. The firts part corresponds to inaccuracies inherent in the argument, the second part is introduced by round-off errors when performing the floating-point Horner scheme and errors due to the representation of the polynomial coefficients $a_k$ as finite computer numbers $\tilde{a}_k$.
We are interested in non-negative quantities $\alpha, \beta \in I\!R^+$ with

$$\left|P_n(x) - \tilde{P}_n(\tilde{x})\right| < |P_n(x) - P_n(\tilde{x})| + \left|P_n(\tilde{x}) - \tilde{P}_n(\tilde{x})\right| < \alpha \cdot \varepsilon(x) + \beta \cdot \varepsilon(l). \quad \text{(C.2)}$$

Numerical values of $\alpha$ and $\beta$ may be computed applying the splitting mentioned above to each individual Horner step. The $k$-th step of Horner's method (exact, using floating-point arithmetic, using interval arithmetic) is given by:

$$\begin{aligned} & t_n(x) := a_n, \quad \tilde{t}_n(x) := \tilde{a}_n, \quad T_n(X) = [\underline{a}_n, \overline{a}_n] = A_n, \quad k = 0, \\ & \left.\begin{aligned} t_{n-k}(x) &:= t_{n-(k-1)}(x) \cdot x + a_{n-k}, \\ \tilde{t}_{n-k}(x) &:= \tilde{t}_{n-(k-1)}(x) \odot x \oplus \tilde{a}_{n-k}, \\ T_{n-k}(X) &:= T_{n-(k-1)}(X) \diamondsuit X \oplus A_{n-k} \end{aligned}\right\} \quad k = 1, 2, \ldots, n. \end{aligned} \quad \text{(C.3)}$$

After $n$ Horner steps it holds $P_n(x) = t_0(x)$ and $\tilde{P}_n(\tilde{x}) = \tilde{t}_0(\tilde{x})$. $\oplus, \odot$ denote $l$-digit machine operations, $\diamondsuit$, $\oplus$ machine interval operations with $l$ or less than $l$ digits. For the intervals $A_k = [\underline{a}_k, \overline{a}_k]$ and $X = [\underline{x}, \overline{x}]$ it is assumed that $a_k, \tilde{a}_k \in A_k$ and $x, \tilde{x} \in X$, respectively. Moreover, the relative error of $\tilde{a}_k$ is assumed to be less than or equal to $\varepsilon(l)$ (e. g. $a_k$ are computed with maximum accuracy using a multi-precision arithmetic). By construction it holds $t_{n-k}(x)$, $\tilde{t}_{n-k}(x)$, $t_{nik}(\tilde{x})$, $\tilde{t}_{nik}(\tilde{x}) \in T_{n-k}(X)$ for all $k$ and all $x$, $\tilde{x} \in X$.
In the sequel we need some more notations. The quantities $\varepsilon_x$ and $\varepsilon_l$ denote some points in the intervals $[-1, 1] \cdot \varepsilon(x)$ and $[-1, 1] \cdot \varepsilon(l)$, respectively. The mapping $\wedge$ is given by

$$\wedge : \left\{ \begin{array}{l} I\!I\!R \to I\!R^+ \\ X \mapsto \hat{X} = \max\{|x| : x \in X\} \end{array} \right. ,$$

and the function ulp is defined by

$$\mathrm{ulp} : \left\{ \begin{array}{l} I\!I\!R \to \{0, 1\} \\ A = [\underline{a}, \overline{a}] \mapsto \mathrm{ulp}(A) = \left\{ \begin{array}{ll} 0, & \underline{a} = \overline{a} \\ 1, & \text{otherwise.} \end{array} \right. \end{array} \right.$$

Using these notations and definitions we now derive algorithms for the computation of the quantities $\alpha_{n-k}$, $\beta_{n-k} > 0$, $\quad k = 0, 1, \ldots, n$ with

$$|t_{n-k}(x) - t_{n-k}(\tilde{x})| \leq \alpha_{n-k} \cdot \varepsilon(x)$$

and

$$|t_{n-k}(\tilde{x}) - \tilde{t}_{n-k}(\tilde{x})| \leq \beta_{n-k} \cdot \varepsilon(l)\,.$$

### C.1.2 Computation of the quantities $\alpha_{n-k}$

We now discuss the computation of the quantities $\alpha_{n-k}$ with $|t_{n-k}(x) - t_{n-k}(\tilde{x})| < \alpha_{n-k} \cdot \varepsilon(x)$. These quantities characterize the error probagation within the individual Horner steps. For $k = 0$ we find immediately

$$|t_n(x) - t_n(\tilde{x})| = |a_n - a_n| = 0, \quad \text{i.e. } \alpha_n := 0. \tag{C.4}$$

and for $k \geq 1$ we get the representation

$$t_{n-k}(\tilde{x}) = t_{n-(k-1)}(\tilde{x}) \cdot \tilde{x} + a_{n-k} = t_{n-(k-1)}(\tilde{x}) \cdot x + t_{n-(k-1)}(\tilde{x}) \cdot x \cdot \varepsilon_x + a_{n-k}\,.$$

Now the estimation

$$\begin{aligned} |t_{n-k}(x) - t_{n-k}(\tilde{x})| &\leq |t_{n-(k-1)}(x) - t_{n-(k-1)}(\tilde{x})| \cdot |x| + |t_{n-(k-1)}(\tilde{x}) \cdot x| \cdot \varepsilon(x) \\ &\leq \alpha_{n-(k-1)} \cdot \hat{X} \cdot \varepsilon(x) + \hat{T}_{n-(k-1)} \cdot \hat{X} \cdot \varepsilon(x), \end{aligned}$$

shows that $\alpha_{n-k}$ can be computed by

$$\alpha_{n-k} := \left(\alpha_{n-(k-1)} + \hat{T}_{n-(k-1)}\right) \cdot \hat{X}. \tag{C.5}$$

That means, starting with $\alpha_n := 0$ we find the error bound $\alpha_{n-k}$ of the $k$-th step using the bound $\alpha_{n-(k-1)}$ already known of the preceding $(k-1)$-th step according (C.5).

### C.1.3 Computation of the quantities $\beta_{n-k}$

The quantities $\beta_{n-k}$ are related to inaccuracies introduced by finite floating-point representations. The computation of these quantities $\beta_{n-k}$ with $|t_{n-k}(x) - \tilde{t}_{n-k}(x)| \leq \beta_{n-k} \cdot \varepsilon(l)$ can be done in the following way:
For $k = 0$ it holds $|t_{n-k}(x) - \tilde{t}_n(x)| = |a_n - \tilde{a}_n| \leq \hat{A}_n \mathrm{ulp}(A_n) \cdot \varepsilon(l)$, i.e.

$$\beta_{n-k} = \beta_n := \mathrm{ulp} \cdot (A_n) \cdot \hat{A}_n \tag{C.6}$$

and for $k > 0$ we find $\tilde{t}_{n-k}(x) = \tilde{t}_{n-(k-1)}(x) \cdot x + 2.1 \cdot \tilde{t}_{n-(k-1)}(x) \cdot x \cdot \varepsilon_l + \tilde{a}_{n-k} \cdot \varepsilon_l + \tilde{a}_{n-k}$ yielding

$$\begin{aligned} \left|t_{n-k}(x) - \tilde{t}_{n-k}(x)\right| &\leq \left|t_{n-(k-1)} - \tilde{t}_{n-(k-1)}\right| \hat{X} + 2.1 \cdot \hat{T}_{n-(k-1)} \cdot \hat{X} \cdot \varepsilon(l) \\ &\quad + \hat{A}_{n-k} \cdot \varepsilon(l) + |a_{n-k} - \tilde{a}_{n-k}|, \end{aligned}$$

i.e.

$$\beta_{n-k} := \left(\beta_{n-(k-1)} + 2.1 \cdot \hat{T}_{n-(k-1)}\right) \cdot \hat{X} + (1 + \mathrm{ulp}(A_{n-k})) \cdot \hat{A}_{n-k}. \tag{C.7}$$

This estimation holds for any $x \in X$, that means especially for $\tilde{x}$.To find the bound $\beta_{n-k}$ for the actual step an update using the bound already known from the preceding step has to be performed according to (C.7).
It is clear by construction that the quantities $\alpha := \alpha_0$ and $\beta := \beta_0$ will satisfy inequality (C.2).

We now want to use the methodology just described to find bounds $\alpha$ and $\beta$ with

$$\left|\frac{xP_n(x) - \tilde{x} \odot \tilde{P}_n(\tilde{x})}{xP_n(x)}\right| \leq \ldots \leq \tag{C.8}$$

## C.2 Program Code Using Taylor polynomials of $\exp(x)$

The program listed now computes enclosures for the coefficients of Taylor polynomials for $\exp(x)$ The enclosures are stored in a file called `out`. This file is used later on as input to the program `experr`.

```
{-------------------------------------------------}
{ Generating enclosures of the coefficients       }
{                                                 }
{             1                                   }
{     a :=  -----                                 }
{      k      k!                                  }
{                                                 }
{ for the polynomial approximation of exp(x) using }
{                                                 }
{              00      k                          }
{    exp(x) = sum   a  x                          }
{             k=0    k                           }
{                                                 }
{-------------------------------------------------}

PROGRAM ExpCoeff;

USE i_ari;
CONST nMax = 20;      { Maximal degree of the approximation }

VAR Coeff: ARRAY[0..Nmax] OF interval;   { Enclosures of ak }
    Out  : FILE OF interval;  { Communication file          }
    k    : integer;                     { Loop variable    }

# Index

# Index of Special Symbols

| | | |
|---|---|---|
| $\mathrm{abs}([x])$ | Absolute value of an interval | ?? |
| $A_B$ | Submatrix of column vectors $a_{*,\beta}$ with $\beta \in \mathcal{B}$ | ?? |
| $\mathcal{B}$ | Set of basic indices | ?? |
| $\mathcal{C}$ | Set of index sets | ?? |
| $\mathbb{C}$ | Set of complex numbers | ?? |
| $c_B$ | Subvector of components $c_\beta$ with $\beta \in \mathcal{B}$ | ?? |
| $\mathrm{cond}(A)$ | Condition number of the matrix $A$ | ?? |
| $d([x])$ | Diameter of an interval | ?? |
| $d_\infty([x])$ | Maximum diameter of an interval vector | ?? |
| $d_{\mathrm{rel}}([x])$ | Relative diameter of an interval | ?? |
| $d_{\mathrm{rel},\infty}([x])$ | Maximum relative diameter of an interval vector | ?? |
| $\mathcal{E}$ | Set of examined index sets | ?? |
| $e^{(k)}$ | $k$-th unit vector | ?? |
| $f^*$ | Global minimum value of a function $f$ | ?? |
| $\widetilde{f}$ | Upper bound for the global minimum value $f^*$ | ?? |
| $\underline{f_y}$ | Lower bound of $f_{[]}([y])$ | ?? |
| $f([x])$ | Range of $f$ | ?? |
| $f_{[]}([x])$ | Interval extension or evaluation of $f$ | ?? |
| $f_{[],c}([x])$ | Standard centered form of $f$ with center $c$ | ?? |
| $f_{[],m}([x])$ | Mean-value form of $f$ | ?? |
| $f_\square(x)$ | Floating-point evaluation of $f$ | ?? |
| $f_\diamond([x])$ | Floating-point interval evaluation of $f$ | ?? |
| $I$ | Identity matrix | ?? |
| $IC$ | Set of complex floating-point intervals | ?? |
| $I\mathbb{C}$ | Set of complex intervals | ?? |
| $IR$ | Set of floating-point intervals | ?? |
| $I\mathbb{R}$ | Set of real intervals | ?? |
| $I\mathbb{R}^*$ | Set of extended intervals | ?? |
| $J_f$ | Jacobian matrix of $f : \mathbb{R}^n \to \mathbb{R}^n$ | ?? |
| $\mathcal{L}$ | Set of neighboring basic index sets | ?? |
| $L$ | Pending list of pairs $([y], \underline{f_y})$ in global optimization | ?? |
| $m([x])$ | Midpoint of interval data | ?? |
| $M^n$ | Set of $n$-dimensional vectors over $M$ | ?? |
| $M^{n\times m}$ | Set of $n \times m$ matrices over $M$ | ?? |
| $\mathcal{N}$ | Set of nonbasic indices | ?? |

| | | |
|---|---|---|
| $N([x])$ | Interval Newton operator for $f : \mathbb{R} \to \mathbb{R}$ | ?? |
| $N_{\mathrm{GS}}([x])$ | Interval Newton Gauss-Seidel operator for $f : \mathbb{R}^n \to \mathbb{R}^n$ | ?? |
| $N'([x])$ | Interval Newton operator for the derivative of $f : \mathbb{R} \to \mathbb{R}$ | ?? |
| $N'_{\mathrm{GS}}([x])$ | Interval Newton Gauss-Seidel operator for the gradient of $f : \mathbb{R}^n \to \mathbb{R}$ | ?? |
| $q^*$ | Coefficients of the deflated polynomial or eigenvector of the companion matrix | ?? |
| $q([x],[y])$ | Distance between two intervals | ?? |
| $R$ | Set of floating-point numbers, floating-point system | ?? |
| $\mathbb{R}$ | Set of real numbers | ?? |
| $\rho(B)$ | Spectral radius of the matrix $B$ | ?? |
| $\mathcal{S}$ | Set of index sets | ?? |
| $\mathcal{V}_{\mathrm{opt}}$ | Set of optimal basic index sets | ?? |
| $X$ | Set of feasible solutions in linear optimization | ?? |
| $x^*$ | Zero or minimizer of a function | ?? |
| $\widetilde{x}$ | Approximation of an exact value $x$ | ?? |
| $\underline{x}$ | Lower bound of an interval | ?? |
| $\overline{x}$ | Upper bound of an interval | ?? |
| $x^{(k)}$ | $k$-th iterate | ?? |
| $[x]$ | Interval | ?? |
| $\langle [x] \rangle$ | Smallest absolute value of an interval | ?? |
| $\lvert [x] \rvert$ | Greatest absolute value of an interval | ?? |
| $\lVert [x] \rVert_\infty$ | Maximum norm for interval vectors or matrices | ?? |
| $([x]_i)_{i=1,\ldots,n}$ | Interval vector of length $n$ | ?? |
| $([x]_{ij})_{\substack{i=1,\ldots,n \\ j=1,\ldots,m}}$ | $n \times m$ interval matrix | ?? |
| $[x]\mathrm{blow}\varepsilon$ | Epsilon inflation for an interval | ?? |
| $[x] \overset{\circ}{\subset} [y]$ | Contained-in-the-interior relation | ?? |
| $[x] \underline{\cup} [y]$ | Hull of intervals | ?? |
| $[x] \cap [y]$ | Intersection of intervals | ?? |
| $[x_{\mathrm{re}}] + i[x_{\mathrm{im}}]$ | Complex interval | ?? |
| $z^*$ | Zero of a polynomial or eigenvalue of the companion matrix | ?? |
| $z_{\mathrm{opt}}$ | Optimal value | ?? |
| $\boldsymbol{\nabla} f$ | Gradient of $f : \mathbb{R}^n \to \mathbb{R}$ | ?? |
| $\boldsymbol{\nabla}^2 f$ | Hessian matrix of $f : \mathbb{R}^n \to \mathbb{R}$ | ?? |
| $\bigcirc$ | Rounding $\bigcirc : \mathbb{R} \to R$ | ?? |
| $\square$ | Rounding to the nearest | ?? |
| $\square(\ldots)$ | Evaluation with maximum accuracy | ?? |
| $\triangledown$ | Downwardly directed rounding | ?? |
| $\triangle$ | Upwardly directed rounding | ?? |
| $\diamondsuit$ | Interval rounding | ?? |
| $\diamondsuit(\ldots)$ | Interval evaluation with maximum accuracy | ?? |
